ABSTRACT

The technique of problem solving abstraction provides an appropriate tool for specifying an interface between the layers of computer hardware and software. Based on this methodology, the types of support and function calls that should be provided to application programs running on micro computers are described with respect to a database resource. The database is integrated with an abstract processor called AM, a machine which focuses on eliminating the problems with portability and reusability of software, imposed by insufficient resource abstraction.

I. INTRODUCTION

Traditionally, computer software evolved in connection with a particular hardware environment, and often assumed features closely related to characteristics of the underlying hardware. These so-called closed systems usually have a unique set of resources in both hardware and software. However, as systems became more general purpose, the requirement for portability and reusability of resources across systems increased and, consequently, the need for creating greater resource abstraction arose [Ref. 1].

The problem of formalizing the relationship between hardware and software resources was first addressed by Yurchak [Ref. 2] whose efforts resulted in the specification and implementation of an abstract machine, called AM.

New data types necessary to represent the abstraction of a bit-mapped display resource were added to AM by Hunter [Ref. 3] thereby creating AM (version 2.0) as a derivation of version 1.0.

This present research again is an extension of the work begun by Yurchak and Hunter with the goal to design and formally specify a portable, reusable abstract database (version 3.0). Its two major objectives are:

- investigate an appropriate methodology to specify an interface between the layers of computer hardware and software;

- find a way for applying such a methodology in order to describe the interface of a computing system with respect to a database.

The following is a modification of the introduction presented by Yurchak [Ref. 2] and Hunter [Ref. 3], and contains some of their ideas which contributes to a better understanding of the background and motivation for this research.

A. THE PORTABILITY PROBLEM

It is well known that porting large programs from one machine to another is an expensive ordeal. It is also well known that once the software has been moved to the new machine, it is anybody's guess whether or not it will be work as before. Even if our program seems to work, we may find it consumes more resources than we expected. Indeed, this may be just as bad as if it did not work at all.

There are a number of reasons why the portability problem is getting worse, not better:

- most architectures, even those which profess to be "language directed," reflect a bias toward making the machine look like what the programmer wants, or toward some engineering goal, such as maximizing the number of devices;

- both languages and machines are related to the data they manipulate in an implementation dependent way;

- language and hardware designers pursue their conflicting goals to the detriment of the poor compiler writer, who, with imprecise tools and methodologies is faced with the job of implementing ambiguous semantics on an informally designed resource.

Although these and other factors do adversely contribute to the imperfect task of moving software from one machine to

11

another, they add their weight to other difficult issues in language design, computer architecture, and software engineering. This study confines itself to treating the issues surrounding the interaction between programmer's view of the world as a problem, and the architect's view of the world as a resource.

The existing problem can widely be described as a matter of unsufficient resource abstraction. And there are examples that demonstrate the advantages brought along by consequently applied resource abstraction. For instance, many operating systems (OS) already provide a uniform and functional interface to the file system, and combined with a high level language and its associated runtime services, achieve a high degree of software portability [Ref. 1]. Current research work in the area of database machines indicates attempts to develop a system that would, like the OS, provide a uniform interface, the first step towards portability and reusability. And this trend should give some reason to be a little more optimistic.

1. Abstraction

"Abstraction" describes the separation of the defining properties of an object from other, unnecessary details about it. A programmer is primarily concerned with solving a problem. Appropriately, the tools at his disposal, programming languages, development aids, the programming environment, form a "problem solving abstraction." The hardware (and some of the software) on which this problem solving abstraction is implemented, however, is an abstraction of a different sort.

12

Addresses, registers, ports, most of the operating system service routines, all provide more or less efficient ways to manipulate the physical resources of the machine, they form a "physical resource abstraction."

The fuzzy area between these two abstractions, sometimes simplistically perceived as the boundary between hardware and software, exposes a number of shortcomings in language design and computer architecture collectively termed the "semantic gap."

As mentioned before, proper resource abstraction plays a major role in the attempt to resolve the portability problem. In areas other than the operating systems, abstraction however, seems to be rather difficult. Processors and visual displays are examples. The inability to establish a meaningful abstraction has impeded the formation of standard functional interfaces to these resources. Operating systems generally do not provide a functional interface to either the processor or the display.[1] Programs which access these resources directly, simply are not portable. High level languages (HLL) partially fill the gap left by OFs for the processor resource. Unfortunately, the interface level is high enough to force many applications to bypass the HLL for efficiency. Special graphics packages that extend the OS provide similar services for the display resource. But despite these efforts, the problem is

_____

[1]Except in the most rudimentary way, OS function calls to the display are usually limited to character and string output.

still far from solved. The lack of formal means to specify the interface that the operating systems, high level languages and graphics packages attempt to provide is a serious shortcoming that impedes portability.

The same applies for database systems, too, which although more recently introduced in computer history not only offer a whole set of different and incompatible database models from which to choose, but also force the implementor to adopt the corresponding query language. The latest development is towards the so-called backend approach that reduces the workload of the host computer in a very impressive way by separating the database part from the mainframe and letting it run as autonomously as possible; but the above described interface problem remains unsolved. Thus, at present the variety that originally was created to optimize a data base to meet the respective goals, strongly interferes with the idea of reusability.

2. The Semantic Gap

The semantic gap manifests itself anywhere a problem solving abstraction touches a physical resource abstraction. A detailed description may be found in Myers [Ref. 4]. He observes that the semantic gap contributes to the cost of software development, software unreliability, inefficiency, complexity, and the distortion of programming languages. Certainly no single development or methodology will eliminate this problem.

14

Narrowing the semantic gap requires significant changes in the fundamentals of computer architecture and language design. We chose to concentrate on three factors which significantly contribute to this problem:

- informally described semantics;
- representation dependent data types;
- arbitrarily designed instruction set architectures.

The implication, of course, is that through increased formalism, the introduction of representation independent data, and a more throughtful treatment of the instruction set, the semantic gap can be narrowed. The balance of this thesis is devoted to describing a methodology for doing just that.

B. THREE WAYS TO NARROW THE SEMANTIC GAP

1. Formalism

The benefits of formalism in the design process have been amply revealed in countless articles treating this issue from the standpoint of software engineering. Our concern will be limited to formalism as it applies to the specification of an abstraction. Various specification methodologies exist, many of which have been used with more or less success in projects of practical significance. But we caution the reader that by "formal" we mean a mathematical rigor rooted in proven theory. The idea of formalism as often applied to software engineering will not do here. A "formal specification" is a complete description of the meaning of an object. It forms the

15

basis for an abstraction and is ultimately a bridge over the
semantic gap.

The benefits of formalism in which we are most inter-
ested are:

- it provides a firm basis for proving our assertions
  about a specification and its implementation;

- it encourages a discipline on the part of the designer
  to be rigorously precise;

- it compels us to find ways of describing things which
  are (implementation) independent.

2. Representation Independence

Conventional machines, in contrast to the AM, force
us, as programmers, to develop our own abstractions of data.
At a time when we are most concerned with developing clean
algorithms the architecture obligates us to worry about status
registers and word length. Certainly someone must ultimately
deal with these physical properties of the hardware, but this
should not fall as an "obligation" upon the programmer. The
programmer should be free to ignore unnecessary detail.

Displays are equally difficult. Often the programmer
is forced to deal with display data at a very low level. In
order to create his display, it may be necessary for him to
work at a level of poking bits out the processor port to the
terminal. By defining data types that include objects which
represent concepts appropriate to visual display processing,
the programmer will be freed to work at a higher conceptual
level.

16

Due to the common nature of this problem, with the database we find ourselves in a situation not much simpler than the one just described. Since a single database is usually designed to fulfill only a very specific task, for instance, running the passenger reservation system for an airline, first of all the logical structure of the database to be created must be developed. This can be done using a data structure diagram which contains all the required entities including the relationship among them. But while this step is achievable without consideration of the later implementation, we have to give up this kind of abstraction in the second phase when the diagram is transformed into a design that conforms to the limitations and peculiarities of a given database management system (DBMS). The programs themselves which may be created in parallel with the development of the logical database structure must apply to the standards of the database type chosen, thus putting the programmer in a similar situation as for all conventional machines.

We will attempt to minimize the dependence of data upon its representation through the use of "abstract data types." Our notion of data is very general. It ranges from integers, to image and database objects, and to program instructions. Data type representation will be hidden and abstract operations will be provided in the same way as with traditional abstract data types. If these data types can be kept representation independent, then portability is aided.

17

3. Intent Expressive Resource Abstraction

Conventional architectures do not permit us to unambiguously express our intent in a program. Artificial data types, combined with typical resource models, force ambiguity and the overloading of data structures. Stack frames are a good example of this. The semantics of the frame combine those of an array and those of a stack. Meanwhile, the whole thing is implemented in memory, with the data types overlaid on an array of fixed length cells.

We claim that applying methods similar to those used to describe abstract data types, we can describe an abstraction of the physical resource of a machine which benefits not only from the formalism used to specify it, but also permits the implementor to clearly interpret the intent of programs written for it.

C. METHODOLOGY

The goal of the research done by Yurchak and Hunter, and now of this thesis is to contribute something of practical significance to the study of software portability by treating an area which has been largely ignored, the design of a formal abstraction for the computing machine itself. We have innumerable high level programming languages, programming environments, graphics languages, database machines (backend processors), query languages, file systems, operating system command interpreters, a whole host of different abstractions tailored to the

18

task of providing us with just enough information to do every-
thing we need to do, and nothing more. So why, then, have we
failed to develop abstractions for the hardware resources, upon
which we are so dependent, which are more than just a collection
of registers, opcodes and some arbitrary rules about how they
interact. A more difficult but certainly more important task
than actually defining the abstraction is developing a methodology
for producing other resource abstractions.

Our method has been to take a naive approach towards all
areas of the design and implementation process not directly
related to the specification itself. We do this for two
reasons. First, we can take for granted the large body of
research in programming languages and computer architecture,
we are designing neither a language nor a processor, even though
"ad hoc" examples were required to complete the implementation.
Second, the research is intended to benefit programmers. Since
it is unreasonable to expect those who may use this method to
understand the theory behind the specification, the key to
understanding the reasons for our design decisions lies in the
way we coded it. Thus, cleverness has been eschewed in favor
of clarity.

Our task in this thesis, then, is to examine a wide range
of issues which impinge on the process of designing and imple-
menting the specification of a database system, and then to
describe how we went about actually doing it.

II. THEORY

The formal specification method used to define the Abstract Machine (AM) is based on algebraic semantics. This approach was chosen because algebras, due to their hierarchical structure, enable us to deal with complex problems or to control complex situations by decomposing them into simpler subproblems, with clearly determined interfaces.

Clean interfaces, on the other hand, provide a sound basis for modifying or combining existing programs, which is our intention in advancing AM from version 2.0 to version 3.0. But algebraic semantics also contribute to solve the portability problem for software systems, since they represent a high level of abstraction which is the only promising means to narrowing the semantic gap.

Abstraction allows us to deal with concepts apart from particular instances of those concepts and to concentrate on the essentials only. Abstract data types are the fundamental elements a formal specification is built upon. Guttag [Ref. 5] states that to describe an abstract data type precisely, its specification must comprise both the syntax and the semantics.

According to Guttag, a formal specification should meet the following criteria, which were taken from Hunter [Ref. 3], if it is to be useful:

20

- it must be restrictive enough to ensure that nothing
  unacceptable to the specifier will meet the require-
  ments imposed by the specification;

- it must be sufficiently general to ensure that few, if
  any, acceptable entries are precluded;

- it must be understandable, so people can work with
  it.

From [Ref. 2], we note that to achieve true portability, we
must be able to demonstrate the following properties in our
implementation:

- the specified semantics actually implemented on the
  source machine are completely unambiguous;

- the implementation on the source machine is "correct."

Thus, our method of specifying must be formal enough to permit
proofs of correctness. Exhaustive testing, however, especially
when dealing with complex specifications, is usually not
feasible and so the only true statement we can make is that
our specification is correct at least with regard to those
tests actually performed.

Algebraic specifications meet the above criteria for achiev-
ing true portability. Here we find a significant body of re-
search already in place in the area of abstract data type
specification. Goguen [Ref. 6] and Guttag [Ref. 5] treat this
topic in great detail. We will not so here. Instead we give
an overview of the important concepts of abstract data types,
and direct the reader to the original works for more in-depth
study of the underlying thoery. Davis [Ref. 7] provides the
theoretical basis for the resource specification method.

21

Davis [Ref. 1] also provides additional background but with an emphasis on practical issues.

A. ABSTRACT DATA TYPES

The underlying principle that gives mathematics the power-ful tool for generalization is its intention to specify the fundamental nature of a system by stating only a few basic properties. In order to describe an entire system by means of a small number of its characteristics it is necessary to find out what exactly these characteristics are and how to state them in terms that define all the systems of this particular category. This can be achieved effectively by applying the technique of data abstraction, which is a synonym for the term "abstract data type."

In general, abstract data types refer to the fact that permissible operations on the data ojects are emphasized, while details about the representation of the data objects are suppressed. Because data abstraction focuses mainly on functional properties but ignores unimportant things like representation details, only some of the many possible func-tional properties have usually to be specified. This allows us to define even complex systems by means of abstract data types, or in other words, via certain sets of data values to-gether with the corresponding sets of primitive operations on those values.

The properties of abstract data types again are specified by algebraic axioms which define all mathematical systems and

provide the basis for deriving additional properties that are
implied by the axioms. This will be discussed in more detail
later in this chapter.

The stack, queue, or list serve as typical examples to
demonstrate how data abstraction works; all of them can be
characterized by simply defining the essential operations that
may be performed on each individual system. For example, a
list could be characterized by operations such as NIL that
creates an empty list, FIRST that returns the first member of
the list, PREFᵀX that adds a new member to the front of the
list, and NULL that tests for an empty list. Using this ap-
proach the programmer need not care about how the list and
its manipulating functions are actually implemented, which
allows him to concentrate on his programming job. And this
principle definition of the list can be used for all systems
of type "list" because the description has been kept very general
by means of abstraction.

Besides providing us with a very important mechanism for
writing well-structured programs, abstract data types make
program modifications easy. As long as the interfaces of the
manipulating functions remain unchanged, internal details may
be modified without affecting other program components in an
unwanted way.

Thus, in applying the methodology of data abstraction we
are forced to clearly specify our intentions, which in many
situations is the stimulus to think intensively about what a

system really is or does, and then to describe the result in an unambiguous manner. Due to its clear style and high level of abstraction, the so-defined system not only is independent of its originator, but is also easier to understand.

B. STRUCTURES

So far we have discussed how to use the mechanism of abstraction in order to handle complex systems but we're primarily concerned with the consideration of the permissible operations on those systems, like the PREFIX operation for lists. In this paragraph we will now examine the more systematic definition of structures. Clocksin [Ref. 8] defines a structure as a single object that consists of a collection of other objects, called components. The components are grouped together to a single structure for convenience in handling them. Thus, a structure can be characterized by the kind of its components and the way they are arranged. Structures are helpful in organizing data since they allow a group of related information to be considered as a single object instead of different ones. The decomposition of data into individual components depends solely on the purpose which is to be achieved in solving the particular problem; so it is up to the programmer to create the structures that contribute most in reaching his intended goal.

To return to our former example, the list, which is a structure itself, what exactly are the kinds of components and their allowable arrangements? For the list as an ordered sequence of

elements the order of the elements in the sequence matters, or
as stated in MacLennan [Ref. 9], the allowable arrangements are
finite linear orderings. The components of a list may be any
terms, including constants, variables, booleans, and lists
themselves. Due to these properties lists can represent prac-
tically any kind of structure that might be convenient for
symbolic computation.

So, for example, if one would like to describe a thing on
the basis of certain attributes corresponding to it, the enumer-
ation of these attributes could be considered as creating a
list by which this thing can be defined:

thing: $attribute_1$, $attribute_2$,...,$attribute_n$

Bringing the attributes, or components of the list, then into
a particular oder and specifying the values they may take, enables
us to create classes of related lists. This can be very useful
in grouping things of the same type together, as it is the case
in all database systems:

class:

$thing_1$: $\langle attribute_{11}$, $attribute_{12}$,...,$attribute_{1n} \rangle$

$thing_2$: $\langle attribute_{21}$, $attribute_{22}$,...,$attribute_{2n} \rangle$

$\vdots \qquad\qquad \vdots \qquad\qquad \vdots \qquad\qquad\qquad \vdots$

$thing_m$: $\langle attribute_{m1}$, $attribute_{m2}$,...,$attribute_{mn} \rangle$

This simple example will be discussed in much more detail in
the following chapters.

In the previous paragraph we have already determined the
primitive operations performed on lists. There are three
classes of operations on structures in general:

25

- <u>constructors</u> which allow us to build a structure in accordance with its predefined characteristics (like PREFIX for lists);

- <u>selectors</u> which allow us to obtain a component from the structure (like FIRST);

- <u>predicates</u> which allow us to determine the arrangement of the components in a given structure and return a boolean value (like NIL).

Depending on the kind of structure one wishes to describe, there is a certain number of operations required; for lists it turns out that just six operations (two for each constructor, selector, and predicate) are sufficient, while, for example, the description of a stack would require only five operations (NEW and PUSH as constructors, POP and TOP as selectors, EMPTY as predicate):

STACK	CONSTRUCTORS	SELECTORS	PREDICATES
empty	NEW	-	EMPTY
nonempty	PUSH	POP	-
		TOP	

But apart from the number of actual operations which is variable, the three fundamental classes of operations remain unchanged for any structure. And there is one more point that should be mentioned: Selectors and constructors invert each other in some cases. For example, for the stack we have

POP(PUSH(stack,X)) = stack

which means that pushing an item X onto a stack and immediately popping it off again leaves the stack unchanged. The same

26

would be true for

$$PUSH(POP(stack),Y) = stack$$

if the same item Y just popped off the stack was immediately pushed back onto the stack again.

But as fine as the inversion of selectors and constructors works for stacks (unrestricted in the case of POP(PUSH)) or for lists, it would not work for queues because items are then added to the rear end while always removed from the front. Keeping these correlations in mind makes it easier to develop our algebraic specification later.

C. ALGEBRAIC SPECIFICATIONS

Specifications are particular and detailed descriptions of things; they contain essential information about the dimensions and peculiarities of the described objects. They furthermore represent a convenient way to describe the generally infinite objects of initial algebras in finite terms if we want to build our abstract data types on an algebraic basis.

Such a specification is also known as "operator signature" and consists of two major components:

- the syntax whose purpose is to define the constants and operations as well as the axioms as intermediate step in developing the semantics.

- the semantics of the data type as part of the realization which is mostly of concern for the implementation.

In mathematical notation a specification can be seen as a triple $<S,\Sigma,\varepsilon>$ where Σ is a S-sorted signature (this means, it

27

is based on the operands of sort S) and ε is a set of Σ-equations. Here $<S,\Sigma,\varepsilon>$ specifies an abstract data type by defining $\overset{\bullet}{T}_{\Sigma,\varepsilon}$ which represents an isomorphism class of Σ-algebras.

An algebraic specification represents something between our intuitive sense of what we want and the actual computer code. This characteristic feature facilitates the translation of our ideas into working programs and narrows the scope of possible interpretation by the application programmer. It also allows us to augment an existing data type by introducing so-called derived operators without the need for rewriting the initial operations, or to extend existing specifications to make their data types available to others, thus avoiding unnecessary redundancy.

1. Syntax Part

The definition of an abstract data type itself should tell us all we need to know for using it effectively. But first of all, how can we be sure that we have selected the correct level of abstraction to begin with? MacLennan [Ref. 9] states that there is in fact no formula for calculating such a correct level, it rather depends on our individual view of the world and our needs at the moment. The chosen approach should, however, guarantee that it really models our abstraction of the part of the world we want to describe.

So, in order to start we list the constants and the primitive operations on the data types to be defined and, in doing so, we create the legal ways in which expressions involving these data types can be constructed.

28

For each primitive operation it is necessary to explicitly state the

- name of the operation;

- type(s) of its argument(s);

- type of value returned;

thereby setting the domain of the arguments and value for each operation:

operation: $(\text{argumenttype}_1, \text{argumenttype}_2, \ldots, \text{argumenttype}_n) \rightarrow \text{valuetype};$

As an example, the syntax for integer addition could be written in the following way:

add(integer,integer) $\rightarrow$ integer;

The syntax chart for the general case which is a modification of the charts usually found in the ADA programming language is shown in Figure II.1.
Figure II.1. Syntax Chart

In short, the purpose of specifying the syntax of an abstract data type is to define

1) the legal forms of expressions, and

2) the way in which the constants and operators can be combined into expressions.

Generally, it seems to be wise to build specifications in a
bottom-up way, which means starting with the most primitive
type of data and then proceeding in gradually reaching a higher
level of abstraction on the basis of the more elementary types
while hiding the details of the lower levels.

But in spite of this approach, each data type has to
be considered independently of its later implementation and
must be treated at any given level as if it were itself a
primitive one which, on the other hand, could lead to some
redundancy.

2. Axiom Part

Having defined the legal (or well-formed) expressions
and the types of values they return in a rather symbolic way,
we next consider the meaning of those primitive operations,
this means, answering the question of what values they in fact
compute when given legal inputs. This is done in the axiom or
property part of the specification which therefore can be re-
garded as a refinement of the preceding syntax definition.

Semantics, in general, deal with the actual realization
of our formal terms; here we are, in accordance with our inten-
tion to use an abstract terminology as far as possible, not yet
interested in any programming language that could do the job,
but prefer to give a set of mathematical equations, or axioms,
which define the meaning of the operations in a way entirely
independent of the final implementation. This approach of
applying mathematical techniques eases the reasoning about
well-formed expressions.

Trying to mathematically specify the axioms we face the problem of what it is that has to be specified and to what extent. As for determining the correct level of abstraction to start with, there is no definite solution to this problem. Basically, we want a set of equations which defines the properties of all well-formed expressions. It is mainly up to the creator of the specification to decide what kind of meaningful interactions between the operators should be included, as long as these equations are complete and define the result of a function for all legal inputs.

For example, the properties for the operation 'integer addition/subtraction'

```
+,- : (integer,integer) --> integer;
```

could be described as follows:

```
a+b = b+a;                    /*commutative*/
a+(b+c) = (a+b)+c;            /*associative*/
a+0 = a;
a+(-a) = 0;
a-b = a+(-b);
```

The final step then would be to find the minimum complete set of equations, which means listing only those equations absolutely necessary to define the properties of the primitive operations, including implicit statements. But since it is sometimes more convenient to directly state equations which, thinking strictly mathematically, are already contained in other statements, it is legitimate to introduce them as so-called derived operators.

31

An example of such a derived operator is the boolean
function IMPLIES:

$$IMPLIES(X,Y) = OR(NOT\ X,Y);$$

which is equivalent to the combination of two simpler functions
containing NOT and OR. By this means we can add new operations
and their defining equations to a data type, whenever it is
useful within the specification.

3. Problems with Algebraic Specifications

From the preceding paragraphs it should become clear
that there is no other way in creating a database for the Ab-
stract Machine except of defining a formal specification first.
This gives us the tool to concisely describe our intentions in
an unambiguous and rigorous manner. But it also forces us to
view the overall problem of what a database actually represents
in a strictly mathematical way. This means, we first must
determine the primitive names that form the syntactic realm and
describe all legal operators. We then must specify the corres-
ponding universe of discourse, which contains our primitive
objects, and the functions that map each name from the syntac-
tic domain to its counterpart in the semantic domain.

Although this approach often does not harmonize with
our intuition, since the human mind tends to be more liberal
than rigorous, it has the distinct advantage of providing us
with a clear structure which is easier to understand and where
each defined operation can be proved correct. We consider
this basic type as the mathematical part of the specification.

This method furthermore has the advantage that, given the operation presently performed and the current state of the machine which corresponds, as Fairley [Ref. 10] states, with ". . . the information required to summarize the status of system entities at any particular point in time, . . . the next state can be determined."

During the research phase for this thesis, however, it became obvious that it often is very difficult to translate relatively simple models of the real world into terms of algebraic expressions. Besides avoiding unwanted inconsistencies the problem centered on the formal requirements for being precise and for specifying the fundamental parts of our database, wherever possible, by stating only the absolutely indispensible basic properties of the system from which all other operations can be derived.

Thus, in the beginning of our work the syntactic specification of the stack operations was studied. But due to its last-in first-out property which is not very helpful for database operations, the stack did not provide the paradigm with which to continue. As a more suitable example that manifested the difficulties in writing an algebraic specification the first-in first-out property of queues was then examined. The specification shown in Figure II.2 is built upon an example given by Fairley [Ref. 10]. In this example (Figure II.2), CREATE and WRITE are serving as constructors that build up or fill the queue. EMPTY and READFRONT describe its behavior.

33

Syntax:

Operation	Domain	Range
CREATE	( )	--> queue
WRITE	(queue,value)	--> queue
READFRONT	(queue)	--> value
DELETE	(queue)	--> queue
EMPTY	(queue)	--> boolean

Axioms:

EMPTY(CREATE) = true

EMPTY(WRITE(queue,value)) = false

READFRONT(CREATE) = error

DELETE(CREATE) = error

$$DELETE(WRITE(queue,value)) = \begin{cases} \text{if EMPTY(queue) then CREATE} \\ \text{else} \\ \text{WRITE(DELETE(queue),value)} \end{cases}$$

$$READFRONT(WRITE(queue,value)) = \begin{cases} \text{if EMPTY(queue) then value} \\ \text{else} \\ \text{READFRONT(queue)} \end{cases}$$

Figure II.2.   A Simple Specification for the Queue

DELETE acts as a modifier to the queue.   While READFRONT always returns a copy of the value sitting in the front position, the operation DELETE actually removes this value from the queue, thereby changing the state of the system.

The problem encountered here is that we are not able to clearly define all of the axioms but instead are forced to make some concessions in accordance with the prevailing state of the queue.   This is caused by the fact that the value presently read from the queue is not necessarily the one entered last (compare Figure II.3).

34

```
--->    ... | n+i |    n+2 | n+1 |  n  |    --->
        ____ _____ . . . . _____ _____ _____
                                  front
                                  value
```
Figure II.3. The Queue Principle

To remain consistent it is therefore necessary to introduce the
conditional "if-else" statement for a part of the axioms which,
on the other hand, takes away some of the simplicity. Compared
with the stack operations where it is sufficient to increase
or decrease a counting device by a number of 1 with each item
added to or subtracted from the stack, the queue operations
require a more sophisticated mechanism to keep track of every
single item in the queue, if one really wants to be precise.
This precision could b achieved by indexing the items when
inserted into the queue. The syntax for these operations is
easily defined, as shown in in Figure II.4.

Syntax:

Operation	Domain	Range
CREATE	( )	--> queue
WRITE	$(queue, value_i)$	--> queue
READFRONT	(queue)	--> $value_j$
DELETE	(queue)	--> queue
EMPTY	(queue)	--> boolean

Figure II.4. Syntax Part for an Index Queue

35

But since we have introduced the index values "$value_i$" and "$value_j$," we now must describe their particular properties in the axiom part. This obviously is a complicated method of describing the relatively simple arrangement of a queue in terms of an algebraic specification, and also proves to be a rather difficult effort. But to our knowledge, there is no really elegant solution to this problem available at the present time.

The previously mentioned indexing methodology can only be simplified by reducing the queue to its basic operations in a similar way as done with the abstract specifications for the natural numbers or integers. Here, for example, the number 1 is expressed by the paraphrase "succnat(zeronat())," and each succeeding number can be described by adding just another "succnat" in front of this fundamental expression. Applying this technique to the queue problem allows us to keep track of every single value written to the queue and read or deleted from it.

So instead of introducing the extra indexing operation, we could integrate the state of the queue ('quaddr') and modify the specification as demonstrated in Figure II.5. On the basis of these few axioms it becomes possible to describe each state of the queue by an appropriate combination of the given operations. The following is an example of this:

```
READFRONT(WRITE(WRITE(INITIALIZE(),v1),v2)) = v1;   /*v:value*/
READFRONT(DELETE(WRITE(WRITE(INITIALIZE(),v1),v2))) = v2;
READFRONT(DELETE(WRITE(INITIALIZE(),v))) = undef;
READFRONT(WRITE(DELETE(WRITE(INITIALIZE(),v1)),v2)) = v2;
```

36

Syntax:

Operation	Domain	Range
INITIALIZE	(qaddr,state)	--> state
READFRONT	(qaddr,state)	--> value
WRITE	(value,qaddr,state)	--> state
DELETE	(qaddr,state)	--> state

Axioms:

```
READFRONT(qaddr,INITIALIZE(qaddr,state)) = undef;
READFRONT(qaddr,WRITE(value,qaddr,INITIALIZE(qaddr,state)))
           = value;
DELETE(qaddr,INITIALIZE(qaddr,state)) = undef;
DELETE(qaddr,WRITE(value,qaddr,INITIALIZE())) = INITIALIZE();
DELETE(qaddr,WRITE(value,qaddr,state)) =
           WRITE(value,qaddr,DELETE(qaddr,state));
if not (INITIALIZE())
then READFRONT(qaddr,WRITE(value,qaddr,state)) =
           READFRONT(qaddr,state);
endif;
```

Figure II.5. A Specification for the Queue Including
              the State

From these examples, where we omitted the arguments "qaddr" and
"state" in favor of clearness, the importance of placing the
parentheses into the correct locations becomes obvious. The
previously defined operations are illustrated in Figure II.6.
A value different from the one residing in the front position
can only be read from the queue after the front value has been
deleted, so a

```
READFRONT(READFRONT(WRITE(INITIALIZE(),v)))
```

```
in (WRITE)                  queue            out (DELETE)
            ┌────┐  ...  ┌─────┬─────┐
----------> │    │  ...  │     │     │ --------------
            └────┘  ...  └─────┴─────┘
              operation INITIALIZE

            ┌──────┐ ...  ┌──────┬──────┐   READ
----------> │val(n)│ ...  │val(2)│val(1)│ ------------------->
            └──────┘ ...  └──────┴──────┘   [ =val(1)]
              momentary state

val(n+1)
            ┌──────┐ ...  ┌──────┬──────┐   DELETE
----------> │val(n)│ ...  │val(3)│val(2)│ ------------------->
            └──────┘ ...  └──────┴──────┘   [erase val(1)]
              change of state
```

Figure II.6.   Illustration of Queue Operations

would return two times the value "v", which is similar to the
corresponding TOP operation for the stack. Although by this
method some of the axioms and the "if-then-else" statements
could be eliminated and furthermore, the requirements for an
abstract specification can be satisfied, it does not seem to
be an elegant solution to the queue problem either. The reason
for integrating this deviation into our research work was to
give the reader a better understanding of the problems that
had to be managed in writing a formal specification for a
database, which is not as simple as the queue.

4. Error Handling

        A major aspect in creating a specification is how to
deal with the situation should the user manipulate the defined

38

operations in a way that would result in an error. Because it
is part of the human nature to fail once in a while, vital
systems tend to be equipped with exception handling mechanisms
which prevent the overall system from breaking down and becoming
worthless, should a predefined type of error occur. This is
also known as fault tolerance or lenience, and represents the
opposite to the more mathematically sound term "strict," where
a function becomes undefined whenever one or more of its argu-
ments are undefined.

Error detection always causes a great deal of problems,
and once having been successful it is a rather philosophical
question of how to proceed, as long as a collapse of the entire
system can be avoided and we get the information that a certain
error has occurred. In general, every attempt to handle this
problem should be based on the understanding that

- any operation which encounters an error is computationally
  meaningless;

- if an operation encounters an error, then any subsequent
  operation which utilizes the erroneous result must also
  return an error;

- errors must not be hidden, but must be known to the user.

These statements were directly taken from Hunter [Ref. 3], since
he considerably modified the error handling routines for the
Abstract Machine (version 2.0), which will be discussed later
in this section.

One interesting but mathematically not indisputable
approach was introduced by Guttag [Ref. 5] with the term

39

"undefined" for equations whose values were not determinable,
for example, when attempting to read an item from the empty
stack

        READ(CREATE) = UNDEFINED.

But since the operation READ can only return a value from the
stack, we either have to treat UNDEFINED itself as a value or
READ as an only partially defined function.

        In the meantime, this problem was solved by Davis [Ref.
1]; his method has been applied to the AM specification and
will be described below.

        Another approach that was used by Yurchak [Ref. 2] for
the initial AM (version 1.0) is to modify the specification and
include an error message. However, it soon became obvious, that
in adding such an error message to the specification, care has
to be taken of all the possible combinations the newly created
error message could be involved in. This is in accordance with
the above listed understanding that, if we get an error, any
operation on it yields an error, too. But it also means that
the number of additionally needed error axioms quickly leads
to an extent which is no longer reasonable.

        To get an idea what dimensions we easily reach in order
to remain consistent, we only have to consider the part of
the specification for natural numbers that deals with the special
error axioms:

```
PREDNAT(ZERONAT() )              = NATERROR;
PREDNAT(NATERROR)                = NATERROR;
SUCCNAT(NATERROR)                = NATERROR:
SUMNAT(N,NATERROR)               = NATERROR;
SUMNAT(NATERROR,N)       .       = NATERROR;          .
SUMNAT(SUCCNAT(M),NATERROR)      = NATERROR;
SUBNAT(N,NATERROR)               = NATERROR;
SUBNAT(NATERROR,N)               = NATERROR;
MLTNAT(NATERROR,X)               = NATERROR;

         :          :                      :
         :          :                      :
```

where NATERROR would have to be specified as the extra operator

class

```
    ERROR
    OP
         NATERROR: --> NAT.
```

Although these error axioms would reduce any term containing an

error to the error message of the appropriate sort, thus

eliminating unwanted elements of the carrier of sort NAT in

the above example, it is obviously not practical to follow this

approach. We therefore succeed with the concept of "undefined"

as introduced by Davis [Ref. 1] and described by Hunter [Ref.

3], since this method allows us to keep the number of additional

axioms manageably low.

The underlying principle is just a different way of

viewing the mapping of elements from a given domain to their

images using a certain function. For example, if we let f be

a function from A to B and let A' be a subset of the domain A,

then f(A') denotes a subset of B, the image of A' under f. We

now consider A' as the domain of our constants and operations

defined in the syntax part of the specification. Furthermore,
we are interested only in the corresponding values they are
mapped to by the function f (see Figure II.7), while ignoring
all the undefined operations in the set A-A', or in other words,
the attempt of mapping an element from the undefined set re-
sults in an undefined value.
Figure II.7. The Problem with Undefined Operations

"Undefined" has the following properties:

-   undef is used to describe the illegal operations;

-   if t = undef then $A(x_1, x_2, \ldots, t, \ldots, x_n)$ = undef;

where "A" is any operator in the specification, and "x_i" is
an expression;

-   any equation containing undef is equivalent to undef;

-   in a realization, if undef is encountered, the processing
    halts immediately and an appropriate error message is
    given.

42

So, instead of listing every single possible NATERROR, all we have to do is add the axiom

    PREDNAT(ZERONAT()) = undef;

to our specification of the natural numbers, which served only as an example for the general case, thereby solving the "predecessor of zero" problem without the introduction of a special error operator. The effect is to restrict the range of free variables that apply to an axiom. This becomes clearer if we look at the following construction, where we substitute ZERONAT() for the free variable n:

    SUCCNAT(PREDNAT(n)) = n;   /*axiom to start with*/
now replace n by ZERONAT()
    SUCCNAT(PREDNAT(ZERONAT())) = ZERONAT();
    SUCCNAT(undef) = ZERONAT();
    undef = ZERONAT();

The evaluation of this axiom shows that substituting ZERONAT() for n leads to an undefined result, which is quite correct, but returns the appropriate value for all free variables otherwise.

Thus, PREDNAT(n) does not exactly belong to the set of constants and operations defined in A' because for some cases, or precisely when n is replaced by ZERONAT(), the value it maps to becomes undefined. We therefore say PREDNAT(n) is only partially defined and must be seen, similar to the POP operation for stacks as a member of the overlapping set of partially defined operations (Figure II.7).

43

Analogously, we receive a similar result for all those specified data types where a faulty user action may turn out as something undefined, like trying to read a value from the empty stack or queue. And since this method has already been applied to the Abstract Machine (AM) by Hunter, this is one more reason to continue with it.

44

III. DESIGN OF THE INTERFACE

Data that is stored more or less permanently to be manipulated by a computer resource represents in some way a simple database, where the software which uses or modifies these data is known as the database management system (DBMS). The difference that makes a database superior to file processing systems which can be considered as predecessors of the database and will be widely replaced by this newer technology, is their capability to provide via the DBMS more information from a given amount of data. The DBMS itself is a complex and usually large program that acts as a data librarian. If we follow the approach presented by Bjorner [Ref. 11], we can view the DBMS as the realization of a certain database model; this then allows us to divide the further treatment into the two parts abstraction and realization, which correspond to the database model and the database management system.

A. BASIC DESIGN PRINCIPLES

In this part of our work we are not yet concerned about the realization but rather concentrate on the problem of how to formulate a useful abstraction of the database resource. As seen, the desired state of abstraction can be reached by extracting the fundamental properties of the object of concern on a level which suits our intentions best. A way to do this

is to look briefly at the design methodology described by Booch [ref. 12] that works for the general case.

1. Definition of the Problem

To get started and to make the overall framework of a database more understandable, models are helpful tools because they enable us to express relatively complex things in a simpler and more evident way. A tree is often used to represent the data structure and the relationship between different members of the database. One of the typical requirements for a database system is to find a certain property among stored objects.

For example, an object with the properties A,B,C,D could be described by a simple tree (Figure III.1), where the object is represented by the root and the properties by the leaves of the tree.

A   B   C   D
Figure III.1.   Tree Representation of an Object

In combining different objects we can create very complicated trees (also called a hierarchy) which represent the relationship in a clear way that otherwise would be difficult to describe. Our goal now is to develop a system that checks the

leaves of the tree for a given condition which could be con-
sidered as a step towards the often applied function of search-
ing for a particular object in a database.

2. Informal Strategy

While still ignoring the question whether such a tree
will actually be represented as a sequential, linked, or in-
verted list in order to see if a certain condition is satisfied
by any of the objects, we can apply the following informal
strategy:

Find all stored members that satisfy condition B.

Figure III.2 gives an example how this informal strategy may
be used. Thus, having shown how the informal method works,
the next step is to find a way of formally expressing this
strategy.

3. Formalization of the Strategy

First we need to identify the objects and their proper-
ties. To do this we look one more time at the informal part:
Find all stored members that satisfy condition B. It is one
of the advantages of the English language that an object is
always represented by a noun, while adjectives describe the
properties of an object. In our simple example this gives us
right away 'member' as the object and 'condition B' as the
required property. Next we have to identify the operation
performed on the object which is not difficult either since
action is described by verbs. In the discussed example, 'find'
is the one looked for. Given the objects, properties, and the

47
	comparand	comparator	indication	storage
initially			0	T_1 $T_2 \ldots T_n$ o o o /\ /\ /\ o o o o o o o o o A C A B C D C D E
set comparand to B and take first tree from storage	B	T_1 o /\ o o A C	0	$T_2 \ldots T_n$ o o /\ /\ o o o o o o o A B C D C D E
check for condition B	B	T_1 o /\ o o A C	0	$T_2 \ldots T_n$ o o /\ /\ o o o o o o o A B C D C D E
since no match get next tree from storage	B	T_2 o /\\ o o o o A B C D	0	$\ldots T_n$ o /\ o o o C D E
check for condition B	B	T_2 o /\\ o o o o A B C D	0	T_n o /\ o o o C D E
since match set indication	B	T_2 o /\\ o o o o A B C D	1	T_n o /\ o o o C D E
reset indication and get next tree from storage	B	T_n o /\ o o o C D E	0	
since no match get next tree	B		0	
since last tree halt				

Figure III.2. An Informal Strategy to Attack the Design Problem

48

operations we may perform on them, we now can describe the
sequence of single steps necessary to 'Find all stored members
that satisfy condition B' by the relational diagram shown in
Figure III.3.

Given this design, we could continue and specify the
interface of each box presented in Figure III.3.   To complete
the formalization part this would, indeed, be necessary. But
we then would also find ourselves right in the middle of the
implementation which is not what we want at this time.   We
therefore stop here short of coming up with a real formaliza-
tion.   The general idea about the possibilities to start
abstracting the resource however should be a little more obvious
by now.
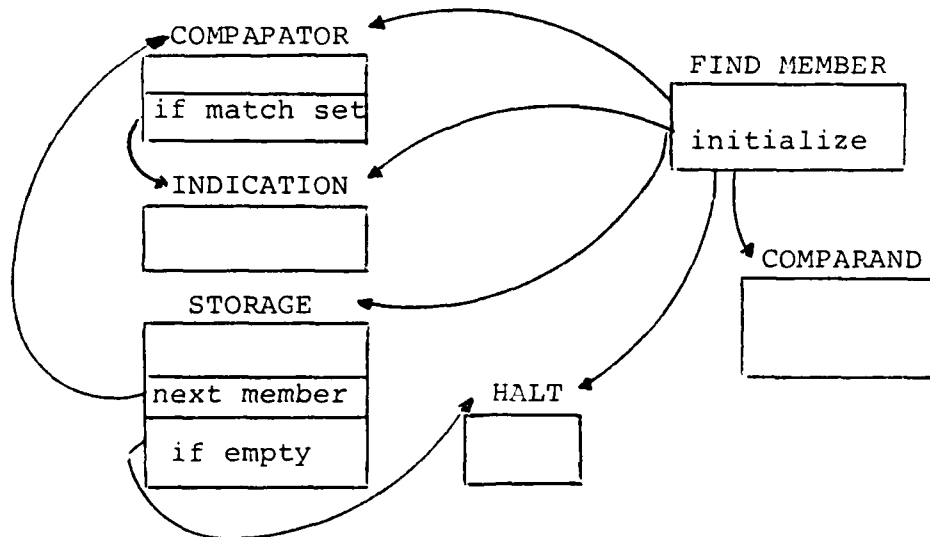

Figure III.3.   Relational Diagram of the Formalized Strategy

B. BASIC DATABASE PRINCIPLES

Before we can start specifying the database resource we need some understanding of the fundamental principles every database, in general, is built upon. Although over the recent years there were various approaches in this area to make database work more efficiently, such as the introduction of the database machine (also known as 'backend'), or the continuing research on the multi-backend database headed by Professor Hsiao at the Naval Postgraduate School, we consider our database as an integrated part of the abstract machine built by extending the present AM. So, in order to formulate a useful abstraction we have to keep it simple and therefore, are interested only in the conventional, single user type of database.

A database is in fact nothing more than an elegant combination of several file processing systems under the control of the DBMS (Figure III.4).
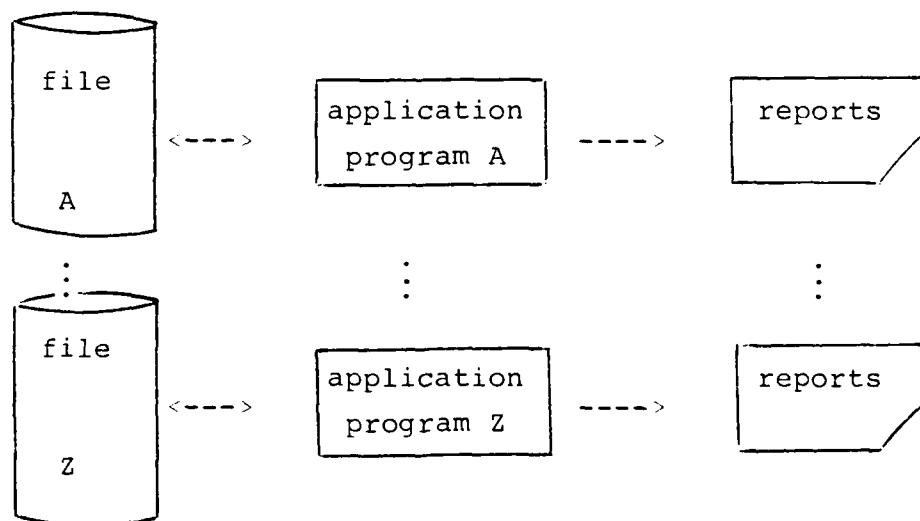

Figure III.4a.   Traditional File Processing Approach

50
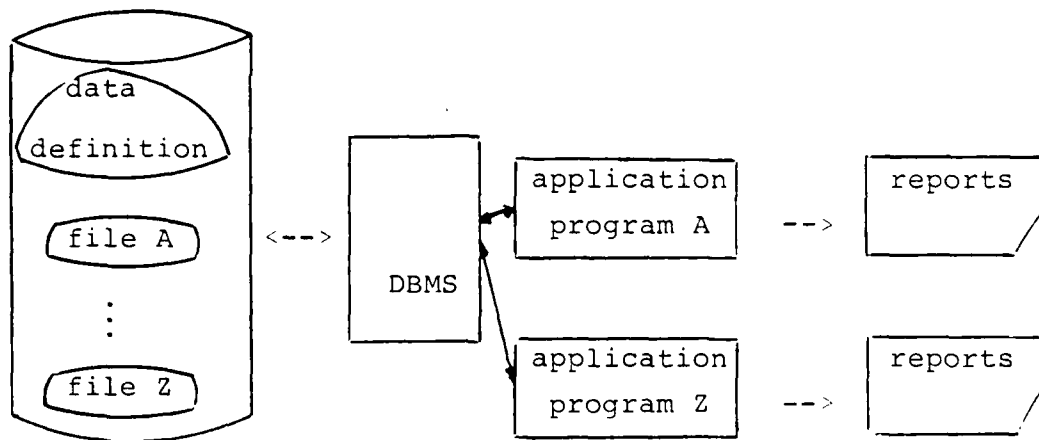

Figure III.4b. Database Processing Approach

For a general view of a database structure we refer to the
architectural description presented by Deen [Ref. 13]. It
is always a major question how to define and treat data that
has to be processed by a machine. In the case of a database
there are as many as five distinct levels data can be viewed
from, namely, in a bottom-up fashion, the

- physical level

- storage level

- global level

- local level

- user level

The meaning of these levels (Figure III.5) is easier to under-
stand if we start with the global level which represents the
center part. This level refers to the overall logical descrip-
tion of the entire database without considering its storage
representation. It shows the logical relationship among the

51
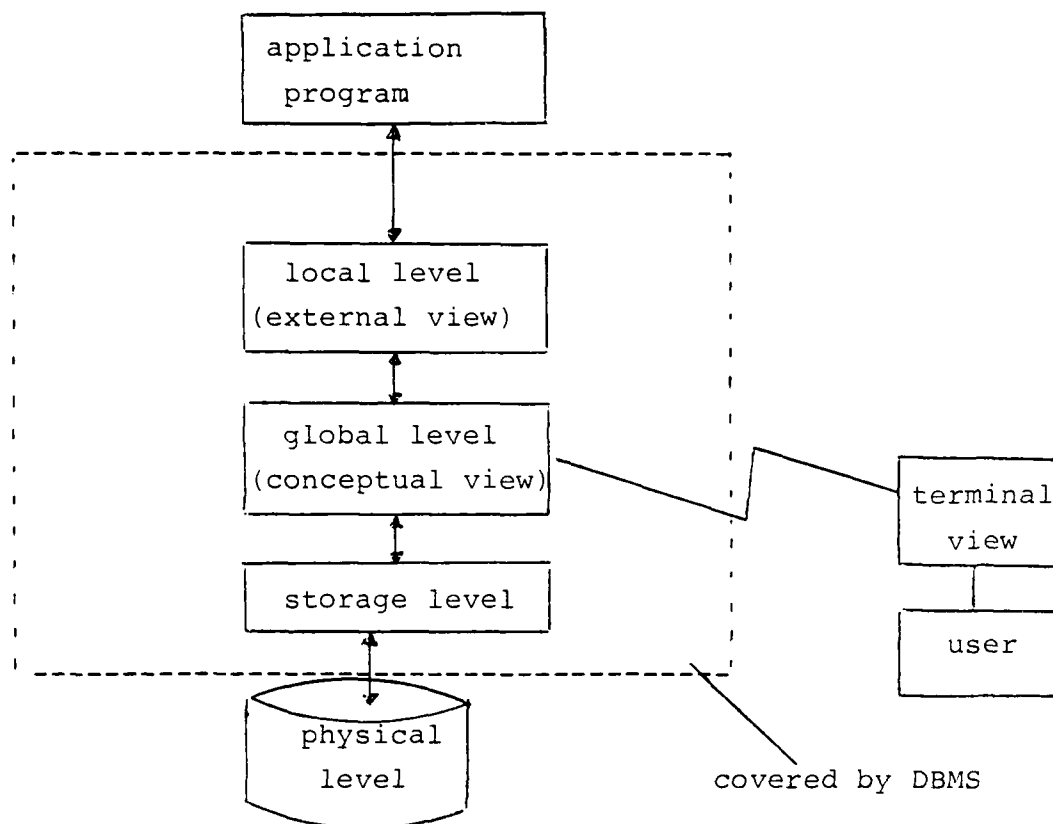

Figure III.5.   Architecture of a Database: The Five
                Levels for Viewing Data

objects of the database and gives the conceptual view of the
system.

The local level provides us with a subset of the database
described at the global level.   It was introduced with the
intention to save the application programmer the inconvenience
of invoking the whole global scheme while he usually is only
interested in a few specific data items, since his need is
local and his view is partial.   So a subset is the application
programmer's view of the database.   It is a logical description

of the part in which he is interested, and therefore represents the external view of the system.

How the data should be organized for storage in the physical device is specified at the storage level which consists of entries for overflows, physical block sizes, and data placement techniques. Access paths can also be specified here.

Whereas global and local level are logical descriptions, the physical level is the physical database itself. The database is stored on physical devices in conformity with the specification of the particular method applied at the storage level, where the purpose of this method is to optimize the overall performance of the database whose logical description is given at the global level. The fifth level is the view of the database as seen by the end user from a remote terminal using a special, high level query language.

Since the view of data at the user level as well as the physical level are not of particular interest for our research, we shall exclude it from subsequent discussions, concentrating only on the application program, the storage, and the conceptual (global) and external (local) view. The application program is stored permanently and is always available to the user. It is usually written once, or maybe a few times, should the database description be changed, and can be invoked by special commands. To manipulate data in the database by the application program a sublanguage, the so-called query or data manipulation language (DML) is needed, one for each host language.

The DML acts as an interface language with the database which enables the application programmer to "navigate" through the database with a search strategy defined by the logical relationships of his data at the local level. An application program containing DML statements has to be compiled either by an extended host language compiler or by a special DML processor followed by a host language compiler.

In contrast to a typical compiler however, this device, the first of three major software pieces, also known as query processor, does not generate machine language but rather a sequence of commands that are passed to other parts of the database management system. The query processor needs to know about the structure of the database, so it can interpret special terms in the context of the particular system. This information about the database may already be built into the query processor itself.

The output of the query processor is fed into the database manager (Figure III.6), where it is translated into terms the third software component in our simplified database blockdiagram, the file manager, can understand, which means, into operations on files rather than on the more abstract data structures of the database description (global level). The file manager may be the general purpose file system provided by the underlying operating system (OS), or it may be a specialized file system that knows about the particular way in which the data is stored in the database.

```
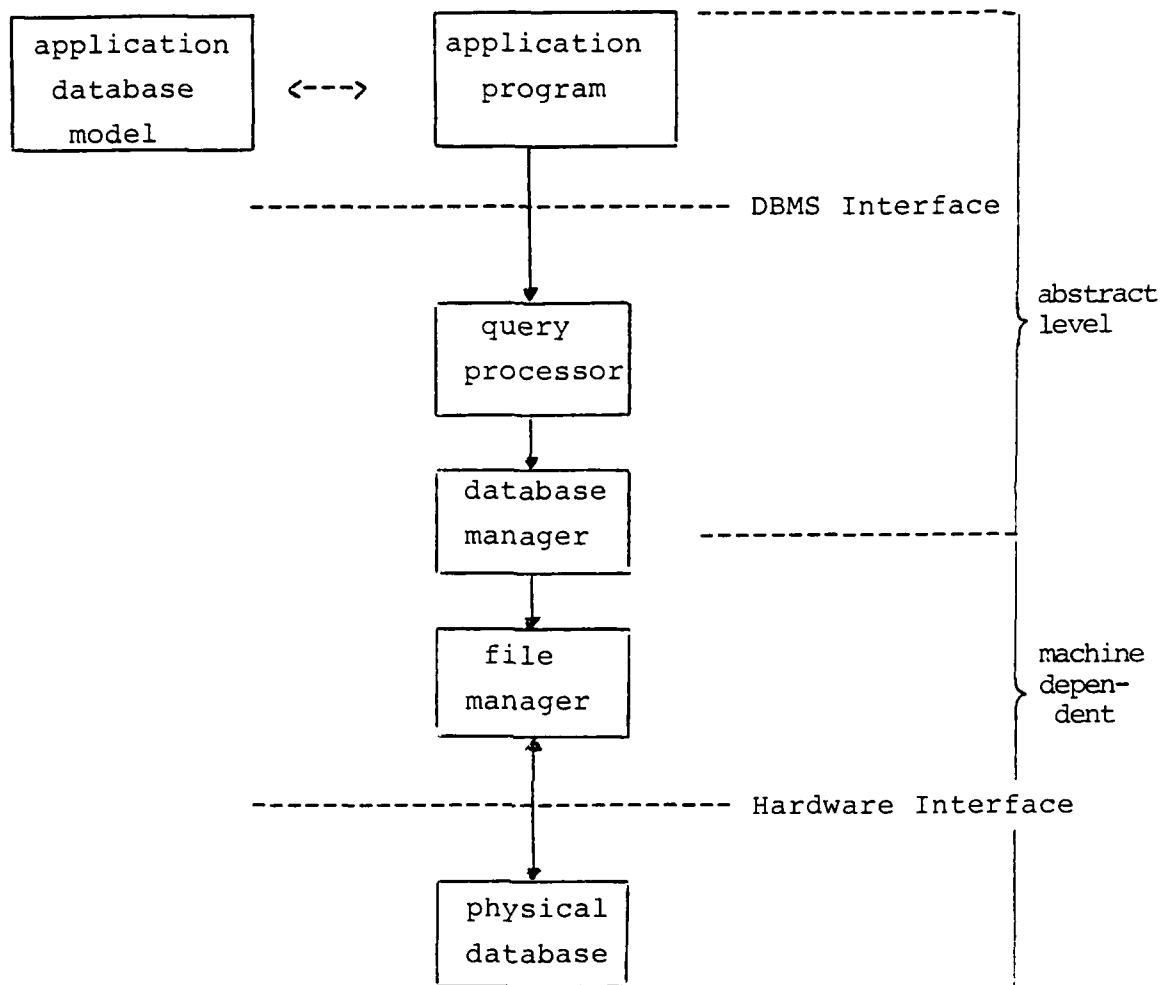

Figure III.6.   Simplified Block Diagram of a
                Database System

The overall software that permits the use or modification
of the data stored is a DBMS which basically covers all the
software components we are mostly interested in.   So this is
the point in the system where the abstract database resource
comes in.

C. THE ABSTRACT DATABASE RESOURCE

The AM database resource replaces two of the items shown in Figure III.6, namely the database manager and the file manager. Figure III.7a shows the block diagram for a database system using AM, while Figure III.7b presents a general view of the AM arrangement within the database system operation.

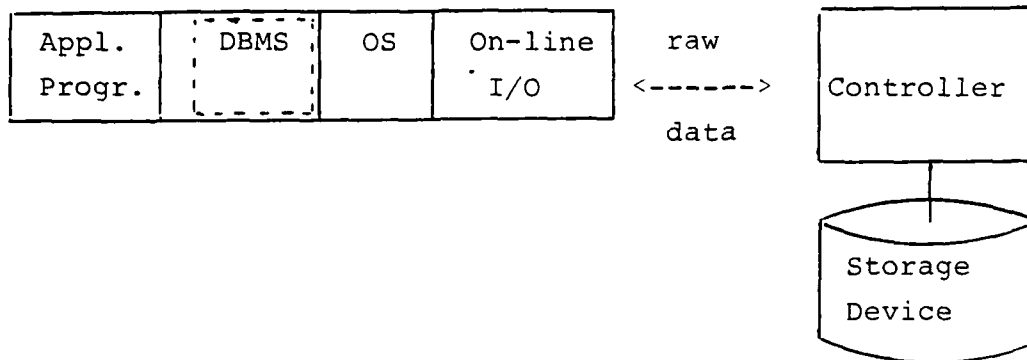

Figure III.7b.   Conventional Database System Operation
                 (Compare Hsiao [Ref. 14])

So AM takes over right at the boundary where the system changes

from working on a more abstract basis to an operation depending

on the particular machine applied.   Since AM does not include

the query processor, it can not be considered as a complete

replacement of the DBMS but instead covers only about two-

thirds of the functions carried out by the DBMS before (Figure

III.7b).   We further recognize that we did not mention another

specialized language, the data definition language (DDL),

which in conventional systems serves as the tool to describe

the entire database once the conceptual scheme is specified.

However, to keep it as simple and clear as possible we do not

want to introduce one more high level language, and therefore

prefer to let this job be done by a special application pro-

gram, using the query processor as mediator.   Since installing

the database is a one time matter this restriction seems feasible.

AM's database primitives are more low level and cover less aspects than, for example, the CODASYL[2] model. But they contain all the fundamental features for creating the database, for updating a given value, for inserting new elements into the database, and for retrieving special data. These operations are considered appropriate for this abstract level, and will be discussed in a later chapter.

In a similar way as for the conventional model, the database manager as the AM interface, which in fact is just a collection of routines, receives as its input the processed query primitives in a still machine independent form. This, however, is the only kind of input the database manager accepts because, since the former DDL entries are now handled by a special application program, there is no need for the manager to have a second input line. It further should be noticed that the security aspect, which means permitting access to certain information stored in the database to authorized persons only, as a task frequently carried out by the manager, has not been taken into account. This step can be justified with the definition of our database as a single user system. Thus, the general idea is to model the database resource 'on top' of the existing AM (version 2.0) by abandoning all of the usually required high level languages like DML and DDL, in order to level the resources with the AM operations, which is the major step for

---

[2]Conference on Data Systems Languages.

58

eliminating the semantic gap. But in contrast to the display

resource defined by Hunter, AM is not entirely able to oper-

ate on the machine independent parts created by a conventional

database system,as long as a separate DDL input is involved.

When dealing with the physical resource the question to be

asked first is what purpose it is supposed to fulfill. From

the programmer's point of view the database should enable him

to:

- create objects, characterized by particular properties;

- connect the objects in a logical way to a file;

- store the objects without consideration of the physical
  storage method;

- operate on any of the stored objects in an uncomplicated
  manner.

In addition to the standard file system where the basic

operations 'open', 'close', 'read', and 'write' will do, a

database must also permit operations for retrieving a distinct

object from the storage, modifying it or checking if a particu-

lar object is stored at all. The details will be described in

the next chapter, but in general, the database represents the

state of all the data stored as files and can be considered as

'just another' resource for AM.

As mentioned before, the programmer has to start his work

with the creation of the logical concept tailored for the very

special kind of database he intends to build. By this logical

design, or model, he copies that certain portion of the real

world which describes his view of selected activities best.

59

But as with every model, its capacity is limited, not all aspects can be covered. Thus, a careful selection of those portions which allow the required logical operations is necessary. The tool for compressing the parts of the real world in such a way that they can be stored within the database is the technique of Aggregation by forming a concept via abstracting a relationship between other concepts, called components, and Generalization by forming a concept via abstracting a class of other concepts, called categories. These techniques will be discussed in the next chapter.

Due to the compression however, some questions now become unanswerable. It is the task of the database designer to make sure that those questions which can no longer be answered are of the kind that never will be asked.

The standard primitives in the real world are the objects and certain properties, where objects as already stated, can be represented by nouns while properties can be considered as adjectives that characterize the objects. We will stick to this notation concerning the primitives throughout this paper because their meaning is more evident and they represent the most abstract level. This is one of the major differences to a conventional database where widely a different terminology is used. The reason for this is that in a database we actually can not work with the real world primitives since a model is not the real world itself. But instead we are working with representations of these primitives. So whenver a transaction

60

from the real world into the conceptual world takes place, the
notation is changed to indicate this step. In a conventional
design the objects are represented by the so-called entities
which are, in contrast to their physical implementation, still
unrestricted by the constraints of the computer. Properties,
in a similar way, are represented by so-called attributes which
serve as a description for the entities and, while properties
are characteristics of an object, attributes are representations
of those characteristics. Thus, attributes are the character-
istics of the data types (objects) themselves and, in fact,
every entity has certain named attributes.

But as stated above, we do not follow this terminological
excursion for the sake of staying as abstract and representa-
tion independent as possible. The intention finally, is to
keep the structure simple, with emphasis on the permissible
operations and to prevent the programmer from leaving the
path of unambiguity.

In AM, database objects are abstract data types. Concep-
tually, database operation is accomplished in the following
way. Objects are initially brought in from the disk and stored
in main memory. To manipulate an object, it is first fetched
from its memory location. It is then used as an operand in
some database operation, and the resultant object is stored
back into memory. At any instance, the memory may contain
several objects, but the terminal is directed to view only
some selected object(s) in accordance with the operation just

being performed. When these operations finally are completed,

the objects temporarily residing in main memory are shifted

back onto the disk under control of the operating system,

which is not to be discussed here.

IV. SPECIFICATION METHODOLOGY

Because our database is considered as an extension of the existing AM we continue the work originated by Yurchak [Ref. 2] using essentially the same specification language which will be described later in this chapter. However, before we proceed with this, first some understanding is required about the approach we took in adding the database to AM. The purpose of the next section is therefore to make the reader familiar with the special methodology applied in order to design this resource, and the chronological steps that were done until finally the specification could be developed.

A. THE FUNDAMENTAL STRUCTURES

To define the operations that legally can be performed on the abstract data types for our database we need some tools to describe our intentions and also to preserve the necessary level of abstraction. Since the complexity of a database is not easily understood, a data model usually is formed as the simplified representation of a particular aspect of reality. In doing so, the questions that arise next are: what are the elements our model will be based on, what actually is it that we would like to represent in a database, or what are the specific aspects of the real world we are mostly interested in? Without claiming to be absolutely correct in the philosophical view of

63

things, the point to begin with is the fundamental structure,
known as the primitives in the real world.

The first phenomenon here is the object, which may be a
thing, a person, an event, an instruction or, in general, some-
thing solid that can be seen or touched. When objects can be
put together under a common but more generalized notation,
they may form an object class. But it must be mentioned that
grouping distinct objects together is only achievable by ignor-
ing their differences at the price of losing some specific
information as a concession to the generalization.

The characteristic qualities owned by an object are its
properties. For the above given examples, it might be the size
of a thing, the name of a person, the date of an event, or the
statement contained in an instruction. All the possible
instances of a property again can be grouped together into a
set defining the domain of all the values this property legally
may take, which therefore will be called 'valueset' in our
specification. This domain represents not just a collection of
numbers or characters but instead has to be considered as the
set of all values a given property can have. For example, for
the object 'person' with the property 'name' the corresponding
valueset would be the collection of all the names that might
be found among people on earth.

An example of how objects and properties are related to
each other is given in Figure IV.1, which is based on concept
developed by Kroenke [Ref. 15:p. 207].

	property name$_1$	property name$_2$	property name$_3$	...	property name$_x$
	:	:	:		:
			94 points		
object$_i$	John	15 years	90 points	...	.
	.	.	37 points		.
	.	.	61 points		.
	.	.	.		.
	.	.	.		.

property$_1$ property$_2$ property$_3$ property$_x$

⌐ ⌐ ⌐ ⌐ valueset of property$_3$
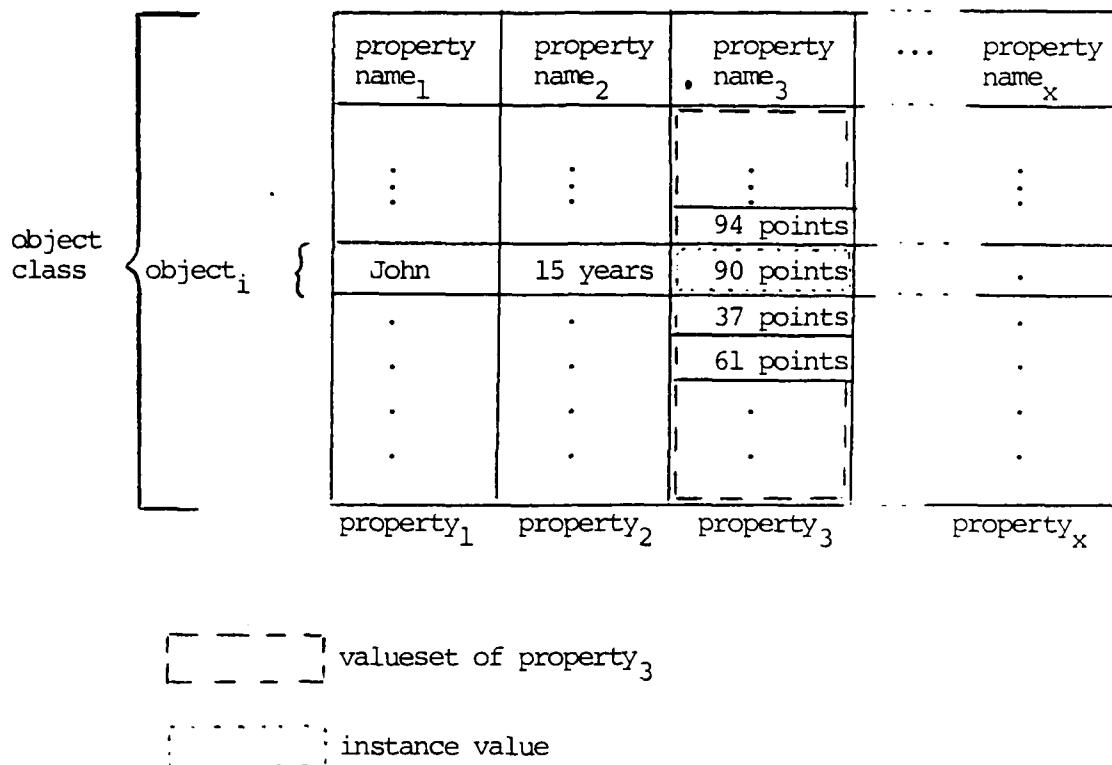

: instance value

Figure IV.1.   Example of an Instance Value as the
              Intersection Between an Object and
              a Valueset

Following this approach we can view the abstract model as con-
sisting of objects and selected properties related to them,
where each single property is composed of a certain name and a
specific value from the predefined domain.   Although one
property may take different values, at any instance it can be
considered as a pair containing a single name and a single
value.   This will be discussed in more detail in Section B of
this chapter.   So in short, we can write as follows:

$$\text{object}_i(\text{pair}_1, \text{pair}_2, \ldots, \text{pair}_n).$$

The basic operations performed on our simple database are:

- create

- insert

- modify

- retrieve

- test for membership

where briefly described:

create--installs a new database;

insert--adds a new object to the database;

modify--changes a certain object by altering one of its
        properties;

retrieve--retrieves an object identified by its particular
        properties from the database;

test for membership--returns a boolean value depending on
        the fact that a particular object does or does not
        belong to the database.

For futher information the reader is directed to the specifica-
tion part of this thesis where the entire operations are defined
in much more detail.

As already indicated in the previous chapter, we adopt the
following view: whenever talking about objects and their
properties we actually deal with primitives of the real world
which are neither easy to handle nor can they be stored in a
machine. To be more precise, in constructing a model we only
work with a representation of the objects and properties but
not with the primitives themselves. In doing so, the portion

of the real world our model tries to catch becomes manageable.
For example, although we can not put the object STUDENT into
a database, it is no problem to store the characterstring
'STUDENT' as a conceptual representation of this object. The
same is true for properties. Since there is no way to store,
for example, 15 YEARS, we instead extract the essential infor-
mation ('15' in this case) which is more convenient.

Furthermore, there are some restrictions to be taken into
consideration. For instance, the programmer should not be
allowed to insert data that does not belong to the valueset of
the specified property, nor modify a non present value. Such
cases have to be covered by a special error handling routine.

B. DEFINING OBJECTS AND THEIR PROPERTIES

One approach to defining an object in terms of mathematical
notation can be found in Hsiao [Ref. 14:p. 67]. Although Hsiao
uses a different terminology, the proposed concept is as
simple as it is clear:

> Let A be a set of 'attributes' and V be a set of 'values.'
> Then a 'record' R is a subset of the Cartesian product
> $A \times V$ in which each attribute has one and only one value.
> R can therefore be considered as a set of ordered pairs,
> or in short notation,
> $R = [(attribute, value)_1, \ldots, (attribute, value)_n]$.

The meaning of this equation is evident, however it does not
necessarily ensure that a certain value will only be attached
to an attribute for which it is explicitly defined in the
corresponding domain. Thus, because our methodology is supposed
to be strictly formal, the given equation can not simply be

67

translated by just changing terms. But we can adopt the basic idea.

The technique we apply must prevent us from mistakenly combining terms that are not defined for each other, and the way we described our properties supports this. Since a property is composed of a pair containing its name and the appropriate set of values which specifies all the legal values for this particular property, only combinations between members of this pair are possible. At each instance such a property identified by a certain name, may take any single value from the corresponding domain, thus representing one specific 'snapshot' lying within the range of feasible combinations. The following example illustrates our intentions.

property 1:

        name: 'age'

        set of values (domain): '10','11','12','13','14', '15'.

property 2:

        name: 'city'

        set of values (domain): 'Monterey', 'San Diego', 'Los Angeles', 'San Jose'.

Legal combinations representing different instances of the given properties would be:

        'age','11'

        'age','14'

        'city','Monterey'

        'city', 'San Diego'

however, combinations like:

'age','Los Angeles'

or 'city','11'

are not possible.

Thus, we have to attack the problem in two successive steps. We start with a particular property name N_i out of the set of all specified names N and with V_i as the corresponding value-set out of the set of given valuesets V. We then can define a property in a similar way as described above as the Cartesian product $N_i \times V_i$ where i>=1.

This ensures that a property won't have other values than those explicitly stated in its domain, where at any instance each property name has one and only one corresponding value. Having generally defined the property $P = N_i \times V_i$, i>=1, we now can easily describe an object as a sequence of one or more property instances P'

$$0 = (P'_1, \ldots, P'_m).$$

Properties by themselves do not make much sense in a database, since it is the object we are interested in. But on the other hand, objects are made out of distinct property instances, and so both the object and its describing property instances represent the primitives in our database. Following a top-down or 'from the simple towards the more complex' strategy in developing a specification for the abstract database, the procedure of creating an object is illustrated in the next example.

property name	valueset			property	'snapshot'
N_1	X	V_1	domain of property$_1$		
		$\vdots$		P_1	$P'_1 = (N_1, V_i)$
		V_m			
N_2	X	V_1	domain of property$_2$		
		$\vdots$		P_2	$P'_2 = (N_2, V_j)$
		V_n			
$\vdots$		$\vdots$	$\vdots$	$\vdots$	$\vdots$
N_z	X	V_1	domain of property$_z$		
		$\vdots$		P_z	$P'_z = (N_z, V_k)$
		V_p			

An instance of an object 0_r can then be described by a sequence of properties P' which themselves contain a name and a particular value, or in other words, it represents several 'snapshots' of the properties P. The previously given description of an object should be clear by now:

$$0_r = (P'_1, P'_2, \ldots, P'_m).$$

A property name will be mapped together with any of the values assigned to the domain of the corresponding property, but will be restricted to only one value at a time when defining a certain object, although a single property name can take different values for different objects.

This probably becomes more obvious when looking at a graphical example, following in some sense the approach to a formal development for data structured in accordance with the different database models given by Hull [Ref. 16:pp. 518-528].

Notation: Let N be the distinguished set of property names and let V be a set of valuesets such that $N \cap V = 0$ (no common elements).

Definition: Then P is the set of all properties, where F maps to each subset P_i of P a property name N_i and a valueset V_i such that the following conditions apply (Figure IV.2):

N (set of property names)
Figure IV.2. Creation of Properties

71

$$F(N_i,V_i)-->P_i;$$
$$g:\ P_j-->V_j;$$
$$h:\ P_j-->N_j;$$
$$F(g(P_i),h(P_i))\ =\ P_i;$$

Restricting these mappings in such a way that values of a certain property can only be transferred from the valueset (domain) which is defined for this property type, properties consisting of different name/value pairs can be created.

Applying $d = <F,F>$ then gives us the tool to describe the first part of the primitives, the properties. Next we need to define the remaining part, the objects. To achieve this, let 0 be a set of objects, where I maps certain pairs $(N_i,V_{ix}) \in P_i$, for $1<=i,x$, to elements of 0 such that $I(N_i,) \neq I(N_j,)$ for every two N_i,N_j belonging to the same object. Then $s = <<P,F>,I>$ $= <d,I>$ can be used to describe any object 0_v by applying I one or more times to different $(N_i,V_{ix}) \in P_i$. The following conditions are true for this mapping (Figure IV.3):

$$I(P_i,\ldots,P_u)\ =\ I[(N_i,V_{ij}),\ldots,(N_u,V_{uk})]-->0_v;$$
$$l:\ 0_v->[P_i,\ldots P_u\ =\ ((N_i,V_{ij}),\ldots,(N_u,V_{uk}))];$$
$$I(l(0_v))\ =\ 0_v;$$

The restrictions added are indeed necessary in order to prevent illegal operations on the sets, which otherwise would be possible. Both methods discussed above lead to the same result, and it was the goal of this section to give the reader an understanding of our strategy in defining objects and their properties. Although this strategy may appear somewhat

0 (set of objects)   P (set of properties)

$I(N_n, V_{hx})$

P_h

0_i

$\cdot N_h$ $\cdot V_{h1}$ P_n
          $\cdot V_{h2}$ $\cdot N_n$ $\cdot V_{n1}$
          $\cdot$ $\cdot V_{n2}$
          $\cdot V_{hr}$ $\cdot$
                             $\cdot V_{ns}$

$I(N_k, V_{ky})$

0_j $\cdot N_k$
            $\cdot V_{k1}$
       1    $\cdot V_{k2}$
            $\cdot$
            $\cdot V_{kq}$
Figure IV.3. Creation of Objects

complex, it represents a serious attempt to handle the data-
base primitives in a consistent way while staying as formal as
possible. And before continuing with the next section which
deals with the creation of object classes, a final note has to
be attached: To distinguish between different objects it is
necessary to include at least one name/value pair that uniquely
identifies each object. This identifier is called the 'key.'
If there is no such key available then there might be the case
where it is impossible to distinguish one object from another.

Objects that are structured in a similar way, which means
they are defined by the same property names appearing in the
same order, can be grouped together to form a class. Such a
class may then be identified by the kind of its property names

73

and the order they are arranged in. However, this is a tedi-
ous method. It is therefore more realistic to introduce a
classname as identifier to distinguish between different classes.

In either case, the kind of identifier is considered to be
an implementation issue and will be ignored at this point.

C. OBJECTCLASSES

A convenient way to handle a large number of objects is by
grouping them together. This can be done with all objects that
are related to each other in a logical sense. These sorted
objects then form a class or subclass of objects, where each
class has its own characteristics that distinguish it from
another. Since objects are composed of several name/value
pairs, the presence of those pairs and the order in which they
appear is the criterion for associating any given object with
a particular class. A graphical example of a subclass is pre-
sented in Figure IV.4. The subclass can be considered as a
two-dimensional scheme with the objects arranged in horizontal
order and the properties as different columns. From this repre-
sentation it becomes obvious that, if a certain property is
not contained in the subclass, none of the objects of that sub-
class can have this property at any instance. In mathematical
notation this could be expressed as:

$$(\text{object}_x \in \text{subclass}_y) \wedge (\text{pair}_z \in \text{object}_x) \longrightarrow (\text{pair}_z \in \text{subclass}_y)$$

where pair_z represents an instance of property_z containing
name_z and one single value from the corresponding domain
defined for property_z.

74

$$\text{property}_1 \ldots\ldots\ldots\text{property}_m$$

	property$_1$ .... property$_m$		
object$_1$	instance$_{11}$	....	instance$_{1m}$
$\vdots$	$\vdots$		$\vdots$
object$_n$	instance$_{n1}$	....	instance$_{nm}$

Figure IV.4. Objects Forming a Subclass

In the same way that objects can be grouped together to form a subclass, several subclasses again can be arranged to form an objectclass. Both are achieved by means of 'generalization,' a technique discussed in the next section.

An objectclass can be considered as a three-dimensional scheme consisting of 'layers' of subclasses as shown in Figure IV.4. To create this figure, turn the subclass in such a way that it fits into the horizontal plane, and then install each on top of the others. Using this method, the arrangement becomes more evident (Figure IV.5). So a subclass equals a certain level of this block whose shape depends on the number of properties, objects, and subclasses being applied. The entirety of all levels or subclasses forms the objectclass. Objects which do not belong to one subclass but have to be present because they are contained in another, are considered as just being left blank in all the subclasses in which they are not represented.
Figure IV.5.   Subclasses Forming an Objectclass

If a certain property is not containted in the objectclass,
none of the objects belonging to that class can have this
property at any instance.   In mathematical notation this can
be expressed as:

$$(\text{pair}_z \in \text{object}_x) \cap (\text{object}_x \in \text{subclass}_y) \cap (\text{subclass}_y \in \text{objectclass}_n)$$
$$\longrightarrow (\text{pair}_z \in \text{objectclass}_n)$$

where, again pair_z represents an instance of property_z con-
taining name_z and a single value from the corresponding domain
of property_z.   So in searching for a particular name/value
pair, first the objectclass can be checked for the matching
property name, then if positive, the subclasses have to be

76

checked, and finally the object that responds to the require-
ments will be localized. By this means a search can be limited
to those objects most likely to contain the requested name/
value pair.

1. Generalization

Generalization is defined as ". . . an abstraction
which enables a class of individual objects to be thought of
generically as a single named object" [Ref. 17:p. 107]. Re-
placing the term 'named object' by the new term 'subclass' this
technique provides a way for conveniently describing how sub-
classes and objectclasses can be constructed. This is true
because, on the next higher level, subclasses themselves by
abstraction build a generalized new 'object,' too, the object-
class (Figure IV.6a).

```
              animals                        (objectclass)

        mammals        birds                 (subclasses)
         /\            /\
      dog  cat     blue   black              (objects)
                    bird
```
Figure IV.6a. An Example of Generalization

By generalization, which can be considered as a bottom-up
technique, it is possible to create the abstraction necessary
for the abstract database (Figure IV.6b).

77

object$_1$

object$_2$

⋮
⠀⠀⠀⠀⠀generalization⠀⠀⠀⟩⠀⠀class
object$_n$

Figure IV.6b. Creating a Class from Objects by Generalization

This bottom-up approach, if <u>all</u> the objects belonging to one
class are included, must then logically be reversible in such
a way that a given class would lead to every single object being
defined by that class. For example, the class 'mammals'
naturally contains also the object 'horse,' and horses belong
to the class of mammals.

2. <u>Aggregation</u>

In order to define the instance properties of an
object, those properties must be determined for every object.
This can be achieved by the technique of 'aggregation' by which
different name/value pairs are grouped together so that they
can be used to describe an object (Figure IV.7).

name/value pair$_1$

name/value pair$_2$

⋮
⠀⠀⠀⠀⠀aggregation⠀⠀⠀⟩⠀⠀object

name/value pair$_m$
Figure IV.7. Creating an Object from 'pairs' by Aggregation

78

Although this method looks like a refinement of the object,
aggregation in fact works the opposite way (bottom-up) and
cannot be treated as an inversion of the generalization.
Furthermore, aggregation is not automatically reversible,
which means an object may have certain name/value pairs, how-
ever these pairs do not necessarily define this specific ob-
ject in an unique way. For example, although a person can be
described by the name/value pair ('age','10'), this particular
pair need not necessarily refer to a person. So in contrast
to the generalization, where an exhaustive installation of
objects belonging to one class would guarantee reversibility,
with aggregation this depends on the way an object is viewed.

Using the method of generalization and aggregation we are
able to draw a picture of the general structure of the data-
base (Figure IV.8). This drawing also clearly demonstrates
that each instance property of any object belonging to a cer-
tain class, must itself belong to that class:

   [((name/value pair) ε object) ⊆ subclass] ε objectclass

D. THE SPECIFICATION LANGUAGE

   1. Grammar

      First developed by Yurchak [Ref. 2] and in a few parts
modified by Hunter [Ref. 3], the grammar used for the specifi-
cation language will be left unchanged to preserve the meaning
of AM as the machine as originally designed. The grammar for
the specification language as found in Appendix A is exactly

objectclass

generalization   subclass   subclass

object$_1$...object$_m$ object$_1$...object$_n$

aggregation

name/value pairs   name/value pairs
Figure IV.8.   General Structure of the Database

the same as used by Hunter. The following description of the
grammar and, in the next section, the preprocessor, represents
an extract of Hunter's respectively Yurchak's work. It was
inserted to give the reader some understanding of the under-
lying fundamentals.

The selected grammar is similar to examples found in the
literature, but the specification language includes some features
usually reserved to programming languages. A specification
with modules called 'spec' is constructed first using this
language while by means of the 'extension' operator it is
possible to combine the specs in a hierarchical order. Each
spec may introduce zero or more new 'sorts,' 'operators' and/
or 'axioms.' A 'sort' can be considered as a data type and
forms an object set from which the operands are selected for
the operators. The elements in a sort are created from the
listed 'operations.' Whenever feasible, one or more constants
are declared in the beginning to provide a basis for other

elements. For example, the constant zeronat() would be such a basis for generating other elements in spec natural.

Sorts introduced in a spec may also be added to an existing spec through 'extension' of the spec(s) that will be taken as the basis, or they may form the primitives for a new 'branch' of the hierarchy. Extension provides the only means of relating the sorts and operators from different specs so that the newly declarated operators refer to both the new sort as well as to any sort from the extension.

Parameterized specifications are permitted but their use is minimized, as their properties are not well understood. Spec string is one representative of this type of specification.

The semantics and the overall structure of the specification must obey certain rules. All symbols must be unique. No symbol may be used unless it has first appeared as the name of a spec, in a sort definition, or to the left of a colon in an operator declaration. Following this rule guarantees that at no time the properties of the object inferred by the name are ambiguous. Thus, the structure of the specification is much like a Pascal program, but more restrictive. In short, there are no self referential specs, and no use of a spec is possible before it has been defined.

The specification language classifies all operators into one of three categories: 'primitive,' 'derived,' and 'hidden.'

- 'Primitive' operators are those which must be implemented to provide a full instantiation of the spec and form the basis of the resource description.

Although not every primitive operation needs to be directly implemented, the full functionality of each primitive operator must be present. It is up to the implementor whether he likes to exclude some of the primitives or some of the operators described by those primitives, as long as full functionality remains available from either set of operators.

- 'Derived' operators are those which can be derived from the primitives. The implementor may ignore these operations because their function always can be performed by the composition of primitives. Their inclusion is merely a matter of convenience. An example would be the derived operators 'or' and 'implies' in the spec boolean, whose functions are entirely covered by the primitive operators 'not' and 'and.'

- 'Hidden' operators are those to which the programmer has no access. They represent abstractions of the machine required to express a certain semantics. It might be convenient to have them in one case, while in another they may be essential to the semantic description. A typical example for a hidden operator is the READFRONT operation in the specification of a queue, as discussed in Chapter II. Here, this operator is required to build meaningful axioms.

The 'if-then' and 'if-then-else' constructs are used to build conditional axioms. Their function follows the same principles as it does in other languages, for instance, in Pascal. This means, when the evaluated 'boolean expression' is true, the 'then' part of the statement applies, otherwise the 'else' part. The 'boolean expression,' finally is defined as

expression meta_relop expression

where the term 'meta_relop' stands for the metalanguage symbols "=" (equality relation) or "!=" (inequality relation), and is used to decide about the truth of the given boolean expression.

So in some sense, the underlying grammar for our speci-
fication language is similar to the ones used for compiler
compilers. In general, the application of a metalanguage
provides an important tool to formulate various aspects of the
developing design, since it can be used as a description for
another language. Simple technical terms, such as 'if,' 'then,'
'else' or 'endif' were introduced to make our intentions more
clear in both the grammar and specification. In order to dis-
tinguish between the metalanguage terminology and the regular
language, metanames always are boldface. A typical represen-
tative for such a metalanguage is the BNF (Backus-Naur Form)
which serves as a notation for describing the syntax of pro-
gramming languages using ordinary technical English, supplemented
by conventional mathematics.

2. The Macro Preprocessor

The main purpose of the macro preprocessor is to con-
dense the amount of language wherever repetitions would swell
the volume of specifications. This technique also improves
readability because those parts of a specification sharing a
common macro definition, can easily be identified. And since
it is based on the same principle, understanding one macro
definition is the starting point for understanding all of them.

As with the grammar, the idea of the preprocessor was
originally introduced by Yurchak when he designed AM (version
1.0). This convenient technique has been continued by Hunter
in developing AM (version 2.0), and it will also be used for

83

the abstract database. The fundamental theory remains un-
changed. In the following section a description of the pre-
processor is given as it was defined by Yurchak [Ref. 2] and
adopted by Hunter [Ref. 3].

The basic form of a macro definition is

replace "text . . ." with "other text . . ."

Since the grammar of our specification language does not re-
quire quotes, they are used as delimiters for definition and
equivalence strings. A macro with arguments appears like

replace (A,B,...,Z) "text . . ." with "other text . . ."

where the formal parameters <u>must</u> be capital letters. An upper-
case letter always denotes a formal parameter to a macro,
since there are no uppercase letters allowed within the spec
itself. Thus, for the definition

```
replace (S)
            "typeof(S);"
with
            "typeS:-->type;
            atomofS: val-->S;
            valofS: S-->val;
```

then the string

```
            typeof(bool);
```

would be replaced by

```
            typebool:-->type;
            atomofbool: val-->bool;
            valofbool:bool-->val;
```

wherever it appeared. The utility of the macro becomes obvious
when we look, for example, at the fetch and store operators,
used to retrieve and store values of any type from/in primary
memory. All AM data types map into a common sort called 'val,'
which is returned from or passed to memory by these operators.
In order to avoid the need for describing big numbers of vir-
tually identical mapping functions, by means of macro defini-
tions it is possible to describe the first data type and then
just list all the others. This feature clearly simplifies the
specification task.

Macro definitions are also excellent for expressing
certain properties of operators such as commutativity, trans-
itivity, etc., which are used throughout a specification.
Instead of writing out the associated axioms repeatedly, which
could prove to be tedious the definition of macros with appro-
priate parameters permits a more readable and explicit expres-
sion of these properties. The following example gives an
illustration:

```
equint: int,int-->bool;
```

If the arguments are equivalent, then the operation should re-
turn true(), otherwise false(). In order to express eqint
as the equivalence relation on objects of type int, three
axioms are needed:

```
equint(i,i) = true();
equint(i,j) = equint(j,i);
implies(and(equint(i,j),equint(j,k)),equint(i,k))
          = true();
```

This by itself would be no reason for concern, but there can
be a variety of relations like this within a specification,
and for each single case these three axioms have to be re-
peated in some way. Macros provide the adequate solution,
since a macro defined like

```
replace(X,S)
          "equivrel(X,S);"
with
          "for i in S
           X(i,i) = true();
           for i,j in S
           X(i,j) = X(j,i);
           for i,j,k in S
           implies(and(X(i,j),X(j,k)),X(i,k)) = true();"
```

enables us to use this definition as a template in which equint
just has to be inserted

```
equivrel(equint,int);
```

thereby transforming equint into an equivalence relation on
int in one step. Note that we are not required to explicitly
specify the type of free variables, since this can normally
be determined by context. We do so in the interest of clarity
because there can be no doubt for which type 'equint' is an
equivalence relation.

V. THE DESIGN

Having an operating AM processor available that already
includes the control and primitive data type operations as
well as the visual display device, the next step towards the
goal of developing a fully operational machine was to add a
database resource which could do a far better job than a
conventional file handling system. With the design of the
abstract database, now a model had to be created that was
appropriate for manipulating data in a way to effectively sup-
port the programmer's requirements. Because a database is a
complicated and complex subject, our intentions were to model
a resource which includes only the fundamental operations as
stated in the earlier chapters. This restriction had to be
introduced in order to keep the time constraints given for this
thesis. The complete specification for AM is presented in
Appendix B.

However, one note of caution has to be added like the one
originated by Hunter [Ref. 3] in his description of the bit-
mapped display system: despite our best efforts to be thorough
and rigorous, this AM specification may still contain some
errors. This is not only so because extending a program written
by others most likely supports this possibility, but first of
all because it is a rather difficult matter to ensure that there
is no ambiguity in the axioms. It also can not be guaranteed

that every portion of the spec is complete so that legal but undesirable implementations would not be permitted.

A. THE DATABASE CONCEPT

In contrast to the graphics part of AM, the database once installed by the application programmer is fairly limited to manipulating data in the predefined way. Creativity in the sense of trying and improving is only possible during the conceptual phase which always preceeds the actual installation. This means the programmer must have a clear concept about what to describe and how to arrange it in the most suitable way before the implementation finally can take place. A database represents a number of data being arranged in accordance with certain characteristics or particular relations of interest to the programmer. The main question to be answered is how to abstract a database to its fundamentals so that a programmer can work with it. Once the basic elements were identified as 'objects' and the 'properties' defining them, the next step was to develop the set of functions controlling the database that would support a natural way of thinking about the intended operations. In order to remain consistent, even the 'property' as the basic component of an object had further to be split into the subparts 'property_id' and 'valueset.'

This approach is certainly different from other methodologies because it required eleven separate specifications just to formally define the database and its abstract elements.

Each specification must be considered as a mandatory step on
which succeeding specs are built. And each spec contributes
in an important way to defining the abstract database resource
and therefore can not be omitted. This number of specifications
naturally caused some problems when translating every single
function, in many cases required only for mathematical reasons
of rigor and without practical usefulness for the programmer,
into logical sets of operations. Although these operations had
to be built in and are now available, it is anticipated that
the application programmer will rather restrict himself to the
more useful operations typical for database manipulations.

From the programmer's point of view, it is not of interest
to retrieve all the values defined for a certain property once
the domain has been fixed. He more likely wants to determine
the name/value pairs associated with a particular object or
find out whether one or more objects meet a given condition.
Due to the underlying method objects are structured this can
be achieved on the basis of list functions that will be dis-
cussed in some detail in the following sections. In general,
we adopt the idea that a database can be considered as a big
list. This approach was finally chosen because it facilitates
our effort to describe the principles of the abstract database.

A standard database has to be created first in the mind of
a programmer, then drawn on a piece of paper and, eventually,
installed on the computer. This sequence represents a typical
top-down approach, starting with the overall database,

89

partitioning it into different classes and subclasses and,

finally, assigning objects to them. This approach keeps the

programmer at a very low level of abstraction, where the com-

puter can not provide much assistance. Adding, for example,

a new object would require us to first specify the particular

class to which it belongs. It would definitely ease the pro-

grammer's effort when he could work on a higher level of

abstraction by using the power of the computing resource to

insert such an additional object without caring about the

specific class it refers to. But although this approach has

some fascinating aspects it was not developed since object-

classes are characterized by the kind of their property names,

and thus have to be specified carefully. The probability of

erroneous entries seemed too high to adopt this concept for

our research.

As stated in Chapter III, we also abandon the introduction

of a data definition language (DDL) and a query language since,

due to their high level, a great deal of the intended abstrac-

tion would be taken away. This becomes quite obvious just by

the fact that there are meanwhile several, non-compatible

query languages established. Because our goal is to specify

one particular part of a database, namely the interface be-

tween the conceptual level and the physical level, we confine

our work to the fundamental principles and focus exclusively

on the essential aspects of the database. For the interested

reader it should however be mentioned that, once AM is completed,

there are plans for the near future to develop a high-level

language for AM, too, which would naturally ease the workload

of the programmer.

We now take a more detailed look at the issues and design

of both the data abstractions and resource abstractions.

B. ABSTRACT DATABASE DATA TYPES

In this section we develop the abstraction of the database

in detail along with all the data types needed to support it.

In addition, we discuss issues concerning the design and

examine how the specification captures the properties of the

abstraction.

One of the problems encountered while writing the specs

for the database was, that in contrast to the previous speci-

fications which mostly operate on single data types called

'atoms,'[3] it became necessary to refer to the set theory which

enables us to deal with single atoms as well as with strings

of atoms. Since a database generally contains composed ele-

ments rather than simple atoms, the 'set' seemed to be the

right means to tackle this problem. However, a set does not

allow the same element to be represented more than once, which

would restrict the operations in an unintended way. We there-

fore preferred to adopt the characteristics of a 'list,' where

no similar limitations exist. This required the installation

of an additional spec list that permits the more complicated

---

[3] An 'atom' represents a problem solving abstraction and
is discussed in Chapter VI.

operations on strings. The list will be described in detail

in Sections C and D of this chapter. But first of all, we

consider the basic steps of how to abstract the database.

1. Property-Identification and Value

Each instance property of an object consists of a name/

value pair which from now on will be referred to as 'property-

value,' containing a particular property-identification ('pid')

and a single value ('val'). Spec property_id expresses the

properties of the 'pid' data type. A 'pid' can be a string of

characters that qualifies as identifying notation for a data-

base property. Different 'pids' are combined to a set forming

the 'pidset' data type which can be considered as the descrip-

tion of the domain for all legal names properties may take.

Spec property_idset models this domain. The operation natur-

ally performed on this data type is creating such a set, start-

ing with an initial 'pid' and then extending it by repeated

application of the union operator with the option of using the

empty set as well as the universe of all sets.

The values associated with a particular property are

covered by spec value. This spec and the combination of its

data type 'val' to a set, the new data type 'valset,' whose

properties are described in spec valueset, are constructed in

exactly the same way as the specs for 'pid' and 'pidset.'

All values which may be meaningful in any context with the

determined property names are permitted. For example, for

the 'pid' age this could be the set of natural numbers from 1

92

to 100, while the 'pid' <u>address</u> might require a set of charac-
terstrings. The joint operations 'unpidset' or 'unvalset'
ensure that there are no redundancies in the same domain.
But it is the programmer's responsibility to create the size
and type of valuesets that fit his intentions best. In this
stage it would be possible to build a domain containing dif-
ferent types of data which, if carelessly applied later, could
lead to an erroneous result.

Both the 'pidset' and 'valset' data types provide a
disjoint operation, and a test for membership and equivalence
(relational operators). Regarding the intersection and union
operations, provision has been made for associativity and
commutativity.

2. <u>Property and Propertyvalue</u>

In order to specify a property in its entirety we need
two parts: a 'pid' that describes the name of the property,
and a corresponding 'valset' which determines the domain of all
the values this particular property can legally have. A
property is represented by sort 'prop' and is always constructed
from the ordered pair 'pid' and 'valset'

prop = (pid,valset).

Spec property lists this data type and the possible operations.

To reduce a property to one of its two fundamental
elements, the operators 'getid' and 'getvalset' have been
introduced. While 'getid' returns the property name ('pid')

93

```
        getid: prop --> pid,
```

'getvalset' returns the domain ('valset') of the property

```
        getvalset: prop --> valset.
```

These two operators can be considered as reversion of the
create operator 'crprop.' In combination with the empty value-
set a property may be created just be defining a certain name,
leaving the final determination of the corresponding valueset
unspecified for the moment.

Spec propertyset provides the data type for different
properties associated to a set and has a similar structure as
spec property_idset or spec valueset. But since every property
consists of the ordered pair 'pid' and 'valset,' by the
'getidset' operator all the 'pids' involved and specified as
'pidset' can be retrieved

```
        getidset: propset --> pidset.
```

Defining the properties for the database in this way was the
result of an analytic process which led to the understanding
that a property indeed is composed of a single element iden-
tifying its type, and a set of values for this type. Since
the sequence is important, we can treat a property as an
ordered pair of single elements. But following this definition,
now a certain property does not make much sense for describing
an object, because it can not be used as a characteristic
criterion. For example,

```
        crprop: 'grade',('A','B','C','D','E','F') --> prop;
```

94

would result in the property ['grade',('A','B','C','D','E','F')]
where 'grade' equals the 'pid' and ('A','B','C','D','E','F')
the 'valset.' Would it be meaningful to describe any object
by this property? It certainly would not, because this is a
general statement about the property 'grade' containing all the
defined values a grade can consist of. A specific object, how-
ever, should only contain a specific value that is character-
istic for it. In Chapter IV we called such a combination a
name/value pair or an instance property. Although we mentioned
this subject before, it is our concern to illustrate the basic
difference between a property and a particular propertyvalue.

Sort 'pval' in spec propertyvalue defines the data type
to resolve the problem stated in the previous example. Opera-
tor 'crpval' enables us to create the required instance of a
property that itself serves as the basis for describing any
specific object. Referring to the above given example

crpval: 'grade','A' --> pval

would now result in the propertyvalue "'grade','A'" which then
can be used for any object that would meet this condition.
Besides the relational operators for equality and ...embership,
as for all composed data types, there are operations available
which return either the first element of the ordered pair,
'getpid' retrieves the 'pid'

getpid: pval --> pid,

or the second element which can be retrieved by the operator
'getval' returning the corresponding value of data type 'pval'

95

MICROCOPY RESOLUTION TEST CHART
NATIONAL BUREAU OF STANDARDS 1963 A

getval: pval --> val.

Since objects usually are described by more than just
one propertyvalue, spec propertyvalueset was introduced. With
its data type 'pvalset' it is possible to combine different
propertyvalues into a set. This is the final step on our way
towards defining an object which will be discussed next. In
order to determine the different properties represented in
such a propertyvalueset, the property names, or 'pids,' are
of major interest. They can be retrieved by the operator
'getpidset' which accepts any 'pvalset' as input and returns
the matching 'pidset'

getpidset: pvalset --> pidset.

Due to the fact that the data type 'pval' consists
of the ordered pair 'pid' and 'val,' and that the combination
of distinguished 'pvals' forms a 'pvalset,' this new data type
is also composed of a set of ordered pairs itself, namely the
set of the ordered pairs 'pid' and 'val.' It therefore was
necessary to add two distinguished membership operations, one
for testing whether a given propertyvalue is contained in a
particular set of propertyvalues

mempvalset: pval,pvalset --> bool

and the other for checking if a given propertyvalueset belongs
to a certain propertyset which includes information about the
'pids' involved as well as the domains for the corresponding
values

96

mempset: pvalset,propset --> bool.

Again, as for all sets, the union operator 'unpvalset'
ensures that there are no redundancies, while the disjoint
operator 'intpvalset' would retrieve propertyvalues contained
in both sets to be checked. Furthermore, the standard opera-
tions for associativity and commutativity have been included
on principle in this more mathematical part of the specification.

3. Object and Objectclass

As mentioned before, the essential element of the data-
base resource is the object. Each of the previously discussed
specifications represents an indispensable portion that finally
enables us to express the data type 'obj' by means of these
more elementary data types. Its properties are specified in
spec object. An object can be considered just as a particular
set of propertyvalues, each containing a distinct 'pid' and a
'val'

$$obj = pvalset = [(pid,val)_1,\ldots,(pid,val)_n].$$

The function that initiates this operation is called 'crobj.'
The kind or number of 'pvals' defining an object is of no
interest for us at this point, although it will be later. So,
theoretically, any combination of 'pvals' could be chosen to
build up an object, even such containing the same 'pid' or
'pval' more than one time which actually would be meaningless.
But since the installation of a database is always preceded
by a rather precise concept, the grouping of different objects

97

into classes then should eliminate the possibility of an incidently induced redundancy on 'pids.'

The reverse operation to creating an object is 'getopvalset' which returns the entire 'pvalset' defining the object

getopvalset: obj --> pvalset

while the operator 'getopidset' retrieves only the corresponding set of 'pids'

getopidset: obj --> pidset.

In general, the type of properties is considered more important for structuring purposes, as this criterion forms a good basis for hierarchically combining related objects to classes (compare Chapter IV, Section C). We therefore did not, as the reader might have expected, introduce an analogous operation which would return all the values of a given object, but instead provided the operator 'getoval' that only retrieves one single value associated with one particular 'pid' of the object

getoval: obj,pid --> val.

Provisions are also made for an equality operator 'eqobj' and a membership operator 'haspval' which checks if a given 'pval' is contained in a certain object.

'Class' is the data type that represents a number of objects that are related in some kind to each other. This type has been discussed in some detail in Chapter IV. Its properties

are now specified in spec objectclass. If we want to insert

an object into a particular class, this can be done by apply-

ing the operator 'insobj' which takes a class and an object

and returns a class now including the new object. We must,

however, ensure that only appropriate objects, which means,

with matching 'pids,' will be inserted. This problem is solved

by defining an operator for retrieving the 'pidset' of a class

('getcpidset') which takes a class as input and returns the

corresponding 'pidset'

    getcpidset: class --> pidset.

Together with the above specified operator 'getopidset' that

accepts an object as input and returns its 'pidset,' the

following axiom takes care of this

```
if eqpidset(getopidset(o),getcpidset(c)) = true()
then
    insobj(c,o) = c;
else insobj(c,o) = undef;
endif;
```

by determining whether the 'pidsets' of the object to be in-

serted and of the class both are equal. If they are, then

the object can be added, if not, the operation becomes unde-

fined and the object can not be added.

A similar approach was taken with the operator 'delobj'

for the deletion of a selected object from a given class. It

had to be ensured that any attempt to delete from a class some-

thing not contained in it was discovered. To solve this

99

problem the membership operator 'memclass' used in the
axiom

```
if memclass(o,c) = true()
then
    delobj(o,c) = c;
else delobj(o,c) = undef;
endif;
```

to first check if the selected object is contained in the given
class. This certainly is not a very efficient way of doing
the deletion, but it avoids 'blowing-up' the machine by an
operation that can not be handled.

The situation where a class is itself contained in
another can be managed by the relational operator 'subclass.'
This provision may be useful when the hierarchical structure
is of importance. In connection with the intersection opera-
tor 'intclass' the boolean value of this relation can easily
be determined:

```
if intclass(c_1,c_2) = c_1
then
    subclass(c_1,c_2) = true();
endif;
```

As in most of the cases the 'if-then' part of this axiom could
be reversed and the axiom would still be meaningful. Here it
becomes obvious that the decision, what axioms to include and
which to omit is a rather difficult matter and depends widely
on the view of the designer. But since there is no sound
recipe for how to proceed, this condition may be a source for

100

potential errors not discovered while the specification is
written.

4. Database

The last data type, 'db,' defined in spec database
represents the highest level and operates on all the data types
previously discussed. So, we have now reached our goal of
combining every single data type from 'pid' up to 'class.' As
the reader might have expected, in order to constrcut a data-
base one or more objectclasses must be available. This is a
mandatory prerequisite since it would not make much sense to
treat a couple of non-related objects like a database that
always represents a particularly structured arrangement of data.
Operator 'crdb' allows us to create a database; it takes a
'class' as its only argument and returns a database. A 'class'
can be extended to any required size by the union operator
defined in spec objectclass. This method not only avoids
meaningless redundancies but also ensures that each 'pid' con-
tained in one of the subordinated classes will be contained in
the database, too.

Since 'db' is the data type of most interest for the
application programmer, all the fundamental database operations
have been provided in this specification. For example, 'getdb-
pidset' returns the set of 'pids' comprised in the database,
which cannot be different from those of the corresponding
classes

getdbpidset: db --> pidset.

101

This is expressed by the following axioms:

$$getdbpidset(insclass(crdb(c_1)),c_2) =$$
$$unpidset(getcpidset(c_1),getcpidset(c_2));$$

which states that, if a new class c_2 is inserted into a database consisting of the class c_1, operator 'getdbpidset' would return the set of 'pids' equal to the joint 'pidsets' of c_1 and c_2 as determined in the right hand part of the equation.

Operator 'retclass' enables us to retrieve a given class from the database, object by object

$$retclass: db,class --> pvalset.$$

This function is more difficult to express in axiomatic terms

```
if and(
     and(
         (getopvalset(o) = pvs),
         (memclass(o,c) = true())
     ),
       (memdb(c,d) = true())
   ) = true()
then
   intpvalset(retclass(d,c),pvs) = pvs;
endif;
```

Here three conditions need to be fulfilled to activate the final statement. First, a given object o must have a particular 'pvalset' pvs, second, this object must be contained in a certain class c which itself has to be a member of the database d. Then the 'pvalset' pvs must also be contained in the database. So the intersect operation of all the 'pvalsets'

of this class c when retrieved from the database, and the particular 'pvalset' pvs must finally return precisely this pvs, since it is the only one contained in both the class and the object.

Provision for another operator has been made that retrieves an object whose 'pvalset' is matched by a given 'pval': 'retobj' accepts a database and a particular 'pval,' and searches the database for objects being defined by this 'pval.' Corresponding objects are then returned

retobj: db,pval --> obj.

A queue mechanism operating in accordance with the 'first-in, first-out' principle manages the case should more than a single object be retrieved. The axiom

```
if and(
    and(
        haspval(pv,o),
        memclass(o,c)
    ),
      memdb(c,d)
  ) = true()
then
    retobj(d,pv) = o;
endif;
```

states that, when an object o with a certain 'pval' pv is contained in a class c which itself is contained in the database d, then, when objects having this 'pval' are searched for by operator 'retobj,' these objects will be retrieved. If

103

there is only one object meeting condition pv, it will be presented as soon as it is discovered; otherwise a number of objects will be put on the queue and can then be retrieved object by object. Although this principle is simple, it ensures that each object with matching conditions can be determined and is available to the programmer at the end of one search.

The operator 'modobj' allows for changing a 'pval' of a given object, modifying it thereby. Three arguments are required: the database, the object itself and the new property-value. The database could have been omitted as an argument, but it guarantees that there actually is a certain structure available. The hard part is to defect any case for which the operation might not be defined, for example, if the given object does not belong to the indic. ted database, or if the replacing 'pval' is of a different type than the original or its value not defined in the domain of the associated property. To check whether all these premises are met, five conditions had to be added that must be satisfied in order to legally carry out the operation. The following axiom deals with these problems:

```
if and(
    and(
        and(
            and(
                memprop(pv,crprop(pd,vs)),
                mempidset(pd,getidset(prs))
            ),
```

```
                    (getopidset(o) = getidset(prs))
                ),
                  memclass(o,c)
            ),
              memdb(c,d)
        ) = true()
    then
        modobj(d,o,pv) = d;
    else modobj(d,o,pv) = unde;
    endif;
```

Going line by line through this axiom, it is stated that

1. the new 'pval' pv to replace the present one has to
    be contained in the property created from the 'pid' pd
    and the 'valset' vs, or in other words, since a 'pval'
    consists of a certain 'pid' and a single 'val,' the
    'pids' will be identical while the 'val' of pv is
    contained in the corresponding 'valset';

2. 'pid' pd must be a member of 'propset' prs;

3. the 'pidset' of object o to be modified must be
    identical with the 'pidset' contained in 'propset' prs;

4. object o must be contained in class c;

5. class c must be a member of database d.

If all these conditions are met, 'modobj(d,o,pv)' is defined

and the operation can be executed; otherwise it would be

illegal and can not be carried out. In short, this axiom

ensures before the operator can be applied, that the new

propertyvalue may be inserted because the entered property_id

is actually present in the object to be modified, and the new

value is defined within the domain of the associated property.

Thus, one instance of this property will be replaced by another

instance also defined for the particular object.

The remaining operators for type 'db' are similar to
the ones discussed for spec objectclass and are the relational
operator for membership 'memdb' and the operator 'insclass'
for the insertion of a class, respectively 'delclass' for its
deletion. As analogously described before, a class can only
be deleted if it is contained in the database; this is expressed
in the axiom

```
if memdb(c,d) = true()
then
    delclass(d,c) = d;
else delclass(d,c) = undef;
endif;
```

If a given class is not contained in the database, it can not
be deleted and the operation is undefined. With the insertion
of a new class this is not quite as simple:

```
if and(
      or(
        memdb(c_1,d),
        memdb(c_2,d)
      ),
       eqpidset(getcpidset(c_1),getcpidset(c_2))
    ) = true()
  then
    insclass(d,c_1) = undef;
    insclass(d,c_2) = undef;
  else if and(
            and(
                memdb(c_1,d),
                not(memdb(c_2,d))
            ),
```

106

```
                    not(eqpidset(getcpidset(c_1),getcpidset(c_2)))
            ) = true()
    then and)                              .
        (insclass(d,c_2) = d),
        (getdbpidset(d) = unpidset(getcpidset(c_1),
        getcpidset(c_2))
    );
endif;
```

Here the axiom defines that if either one of two objectclasses c_1, c_2 is already a part of the database d and both have the same set of property_ids 'eqpidset(getcpidset(c_1),getcpidset(c_2)),' then there is no way of inserting any of these classes since they are already represented. If one of the classes c_1 is part of the database while the other (c_2) is not and they do not have the same set of property_ids, which means they must be different then it would be a legal operation to insert the one not yet contained. The property_idset of the database must then be extended by the newly added 'pids'; this is done by the joint operator 'unpidset.'

These operations define spec database and thereby the fundamental part of all the individual specifications required for mathematically[4] describing the database. The remaining portion of Appendix B represents the transition towards corresponding operations that finally can be translated into machine instructions.

_____

[4]Algebraic semantics describes *what* has to be done rather than *how* to do it.

C. SPEC PARAMETERIZATION

The characteristic properties of a list allow us to des-
cribe the essential database operations of retrieve, insert,
modify, and delete in a convenient way. Lists not only provide
a clearly structured method for treating strings of variable
length but also support recursive operations, which proves to
be very useful for searching the database. It is the purpose
of this section to show how these basic operations can be
managed by application of the list theory, while in the next
section we describe its usefulness for our particular data-
base design.

This, however, should not be seen as the attempt to narrow
the spectrum of possibilities for the implementor or to guide
his attention into one specific direction, since our methodology
focuses on representation independence. The only reason for
choosing this approach is that it provides an evident way to
express our intentions.

Since the contents of our database can be considered as
strings rather than as single atoms, it was necessary to make
provision for this by introducing the additional spec list with
data type 'elm.' This spec is a representative of the earlier
mentioned parameterized specifications. It was used to define
the special list operations including the recursions which
offer a convenient way to carry out searches. Spec list allows
the treatment of all previously described specifications as if
they were of type 'elm,' simply by using a combination of spec

108

list with each of the former specs. For example, by applica-
tion of the first discussed spec property_id using 'list
(property_id),' now the new spec pidlist can be created which
enables us to treat the initial data type 'pid' as 'elm' and
the operator 'eqpid' as 'eqelm.' This procedure has the advan-
tage that we can stay within or continue with the logical
structure of AM specifications as they were developed by Yurchak
[Ref. 2] and Hunter [Ref. 3]. It furthermore is a contribution
to the clarity and simplicity of our work since we can adopt an
available technique.

The typical list operators are 'nullst' which returns an
empty list, 'firstelm' which returns the first element of a
given list, 'firstlst' which retrieves the first list of a
given list of lists, and 'restlst' which returns either the
remaining elements or lists of a given list, except the first
one. The meaning of these operators is expressed in several
axioms

```
firstelm(makelst(k)) = k;
restlst(makelst(k)) = nullst;
```

where 'makelst'is itself an operator which takes a single
element and returns a list containing this element as its
only member

```
makelst: elm --> list.
```

Should a given list be empty, so that there is no first
element or any rest, the application of these operators leads
to an undefined result by the corresponding axioms.

109

In contrast to 'makelst,' the operator 'makenewlst' requires a list as an input and returns a list again. By this operator it then is possible to express the operation 'firstlst' in the following axiom:

firstlst(makenewlst(l)) = l;

thus operator 'makenewlst' has an important function in order to indisputably describe the meaning of operator 'firstlst.' In fact, it sometimes is necessary to define an additional operator just for the purpose of expressing an already developed operation in an unambiguous way.

Operator 'catlst' allows us to concatenate two lists into one and also serves as a significant tool for illustrating the meaning of the previous operations. The following axioms give an example:

firstelm(catlst(makelst(k),l)) = k;
firstlst(catlst(l_1,l_2)) = l_1;
restlst(catlst(l_1,l_2)) = l_2;

These are just a few representative axioms dealing with the fundamental list operations. Many more are required to actually express our intentions. They can be found in Appendix B. Again, we face the initially encountered problem of how to ensure that we did not miss any axiom of importance which possibly could result in an unwanted operation. So there is indeed no guarantee that our perception of the specified resource is precisely what the specification describes.

Some other, not necessarily typical list operations also had to be introduced for the particular purpose of handling all the recently defined database operations. Because these operators are more complicated they will be discussed in some detail in the following. Each of them requires searching the database first before it can be applied or successfully terminated. Consequently an iterating process was needed that could do the job. Due to its simplicity the recursive[5] approach was chosen, which in general requires a termination condition and a certain pattern that reduces the overall problem to smaller, solvable subcases. So, what we actually created was an archetype for each of the functions, containing its syntax and semantics, where the recursive definition can be considered as the prototype (compare [Ref. 9]).

Operator 'delst' is a function that accepts two lists as an input and returns a list. The first list is the one to be deleted from the list of lists entered as the second argument

e.g., $delst[(1_b),(1_a,1_b,1_c)] -- (1_a,1_c)$ /*1_i: list */

Two conditions have to be met before this operator can legally be applied: The list from which we delete must not be empty, and the one being deleted must be contained in it, otherwise 'delst' becomes undefined. The axiom

---

[5]Other approaches, like repeatedly applied function calls, could also do the job.

111

```
        if or(
            eqlst(l_2,nullst()),
            not(memblst(l_1,l_2))
          ) = true()
    then
        delst(l_1,l_2) = undef;
    else if eqlst(l_1,firstlst(l_2)) = false()
    then
        makenewlst(catlst(firstlst(l_2),delst(l_1,restlst(l_2))));
    else makenewlst(restlst(l_2));
    endif;
```

takes care of these cases. The next step then is to find the
particular list l_1 which shall be erased. The only way to do
this is by testing list after list of l_2 for identity with l_1.
If the one being examined ('firstlst(l_2)') is not identical
with the one to be deleted (l_1), it can not be thrown away but
instead has to be saved, and the operation must be repeated
with the rest of list l_2. This is achieved by the 'else-if' part
of the axiom, until the identity is finally reached. By the
'else' part, only the rest of list l_2 is then concatenated to
the previous portions of l_2, while the list searched for will
be eliminated.

Example:
```
        if or(
            eqlst[(l_a,l_b,l_c),()],
            not(memblst[(l_b),(l_a,l_b,l_c)]
          ) = true()
    then
        delst[(l_b),(l_a,l_b,l_c)] = undef;
```

since this condition does not hold in this example, the
'else-if' part will be checked:

else if eqlst $[(1_b),(1_a)]$ = false()

then

makenewlst[catlst$((1_a)$,delst$((1_b),(1_b,1_c)))]$;

where 'delst' initializes the repeated application of the
operation. During the second run the 'else-if' condition
becomes true

eqlst$[(1_b),(1_b)]$ = true()

and the 'else' part therefore is activated

makenewlst(1_c);

this leads to the concatenation

catlst$(1_a,1_c)$;

which is the final result in this case.

This operation still retains the necessary level of abstraction
since it would work for every data of type list. The structure
of the database, as described in the eleven specifications at
the begining of this chapter, supports the application of the
list theory. This issue will be discussed in the next section.

Operator 'getlst' takes a list 1_1 of lists and a particular
list 1_2 as input and returns the list corresponding to 1_2

getlst$[(1_{a1},1_{a2},1_{b1},1_{b2}),(1_{b1})]$ --> 1_{b2} /*1_i: list$_i$ */

It is expressed in the axiom

if or(
    eqlst$(1_1$,nullst()),
    eqlst$(1_2$,nullst())
) = true()
then
    getlst$(1_1,1_2)$ = undef;
else if eqlst(firstlst$(1_1),1_2)$ = true()

```
then
    getlst(l_1,l_2) = firstlst(restlst(l_1));
else if eqlst(firstlst(restlst(l_1)),l_2) = true()
then
    getlst(l_1,l_2) = firstlst(l_1);
else getlst(restlst(restlst(l_1)),l_2);
endif;
```

The meaning may not be obvious at the first glance, so we will
explain it. The underlying principle is that we consider a
list of this type as a combination of several pairs of lists.
Thus, entering a list of lists $(l_{a1},l_{a2},l_{b1},l_{b2})$ and one part
(l_{b1}) of such a pair shall result in retrieving the matching
second part of the corresponding pair from the list $(l_{a1},l_{a2},$
$l_{b1},l_{b2})$. Again, precaution has to be taken for cases where
this operation can not be performed. For example, when either
of the lists is empty, then 'getlst' becomes undefined. The
axiom is constructed in such a way that always a pair of lists
from the first list is checked against the second li·t which
itself represents only one half of a pair. Should the first
part of the list ('firstlst$(l_{a1},l_{a2},l_{b1},l_{b2})$') be identical with
the second list (l_{b1}), then the matching part of the pair
('firstlst(restlst$(l_{a1},l_{a2},l_{b1},l_{b2})$)') will be returned as the
result. Should the second part of such a pair ('firstlst
(restlst$(l_{a1},l_{a2},l_{b1},l_{b2})$)') be identical with list (l_{b1}),
then the first part of the corresponding pair will be retrieved.
If no match occurs the 'else' condition applies, the recursion
is activated and the remaining pairs from the first list will

114

be checked against the second list. So in case l_2 was not

contained at all in l_1, list l_1 will eventually become empty

and, since it is not possible to retrieve a part of a pair that

does not exist in the given environment, the operation must

become undefined at that time. This is exactly what will

happen by means of the termination condition for the recursion.

Example:

```
    if or(
        eqlst[(l_a1,l_a2,l_b1,l_b2),()],
        eqlst[(l_b1),()]
      ) = true()

    then

        getlst[(l_a1,l_a2,l_b1,l_b2),(l_b1)] = undef;
```
since this condition is not true, the 'else-if' part will be
checked:
```
        else if eqlst[(l_a1),(l_b1)] = true()
```
which is not true either, so the next 'else-if' condition will
be checked:
```
        else if eqlst[(l_a2),(l_b1)] = true()
```
since this is false, the 'else' part is activated
```
        else getlst[(l_b1,l_b2),(l_b1)];
```
which initializes the repeated application of this operator.
In the second run, the first 'else-if' condition becomes true
```
        else if eqlst[(l_b1),(l_b1)] = true()
```
so the following statement will be executed:
```
        then

            getlst[(l_b1,l_b2),(l_b1)] = l_b2;
```
returning l_{b2} which is the list that corresponds with the
second argument l_{b1} in the described example.

The next operator, 'sofirstlst' (set of first lists), takes a

list as input and returns a list or, more precisely, it requires

a list of lists and gives a set of lists back

115

$$\text{sofirstlst}[l_{a1}, l_{a2}, l_{b1}, l_{b2}] \;\; \text{-->} \;\; (l_{a1}, l_{b1}).$$

This special function was introduced to manage the operations where a set of first lists shall be retrieved:

```
if ltnat(lenlst(l),succnat(succnat(zeronat())))) = true()
then
    sofirstlst(l) = undef;
else if eqnat(lenlst(l),succnat(succnat(zeronat()))))
    = true()
then
    sofirstlst(l) = firstlst(l);
else catlst(firstlst(l),sofirstlst(restlst(restlst(l))));
endif;
```

where the criterion for the operation to be defined is, that the list must have at least two elements that themselves are lists or lists of lists, which is stated in the 'if-then' part of the axiom. This is so because it would not make sense to apply 'sofirstlst' to anything else besides a list cf lists. The termination condition will be reached when the list has been reduced to just two sublists ('else-if' part). In all the other cases the first element of the first list ('firstlst (firstlst(l))') will be concatenated to the iterated operation 'sofirstlst,' now applied to the remaining portion containing all other lists except the first one. Thus, finally, this operator returns every first list from the sublists of list l.

Example:
```
if !lenlst(l_a1, l_a2, l_b1, l_b2) < 2] = true()
then
    sofirstlst[l_a1, l_a2, l_b1, l_b2] = undef;
```

116

since the length of list $1 = 4$, this condition does not hold
and the 'else-if' part is tested
> else if [lenlst(l_{a1},l_{a2},l_{b1},l_{b2}) = 2] = true()

which is not true either, so the 'else' part is applied:
> else catlst[l_{a1},sofirstlst($l_{b1}l_{b2}$)];

thereby initializing the repeated application of the operation.
In the second run, the 'else if' condition becomes true,
since (l_{b1},l_{b2}) now has length = 2, so the 'then' statement
is applied:
> sofirstlst(l_{b1},l_{b2}) = l_{b1};

which leads to
> catlst[l_{a1},l_{b1}] = (l_{a1},l_{b1})

thereby returning the set of first lists from the given
list 1.

The last operator to be discussed is called 'retobjlst'; it
takes two lists as an input and returns a list. It was intro-
duced with the intention to retrieve all the lists which meet
a particular condition

> retobjlst[((l_{a1},l_{a2},l_{a3}),(l_{b1},l_{b2}),(l_{c1},l_{c2},l_{c3})),(l_{b2})]
> $\longrightarrow$ (l_{b1},l_{b2}).

So in some sense, this is the most useful operation because it
allows us to search a big list for certain sublists without
having to remember all the details about the sublists. The
axiom is short:

> if eqlst(firstlst(l_1),nullst()) = true()
> then
> > retobjlst(l_1,l_2) = nullst();
> else if intlst(l_2,firstlst(l_1)) = l_2
> then
> > catlst(firstlst(l_1),retobjlst(restlst(l_1),l_2));

```
      else retobjlst(restlst(l_1),l_2);
      endif;
```

and states that, if the overall list to be searched (l_1) for a sublist is empty, this list can not be contained in it. Thus, the result is the empty list itself ('if-then' part), which also serves as the termination condition for the recursion. Should the intersection between the entered list l_2 and the first list of l_1 be equivalent to l_2, the entire first list of l_1 will be concatenated to the repeated operation now applied to the remaining lists of l_1 ('else-if-then' part). This en-sures that the list will be completely scanned since more than one of the contained sublists could meet the given condition comprised in l_2. If l_2 does not occur in the particular list being searched at the moment, the intersection of both can not be equal to l_2, and the 'else' part is activated. In this case the operation continues without saving the non-matching portion of l_1. When finally terminated, a concatenated list is available that comprises every single list of l_1 meeting the predefined requirement.

Example:
```
    if eqlst[(l_{a1},l_{a2},l_{a3}),()] = true()
```
since this first list of l1 is not empty, the condition does not hold and the 'else-if' part is tested
```
    else if intlst[(l_{b2}),(l_{a1},l_{a2},l_{a3})] = l_{b2}
```
does not hold either, so the 'else' part is applied:
```
    retobjlst[((l_{b1},l_{b2}),(l_{c1},l_{c2},l_{c3})),(l_{b2})]
```
which initializes the repeated application of 'retobjlst.' In the second run, the 'if' condition is still not true, so

the 'else-if' part is tested

    else if $intlst[(l_{b2}),(l_{b1},l_{b2})] = l_{b2}$

since the condition holds, the 'then' statement is executed

    then

        $catlst[(l_{b1},l_{b2}),retobjlst((l_{c1},l_{c2},l_{c3}),(l_{b2}))];$

which, again, initializes 'retobjlst.'

In the third run, this leads to the application of

    $retobjlst[(),(l_{b2})]$

but now the 'if' condition is true and the entire operation

results in the concatenation of $[(l_{b1}),(l_{b2})]$ with the

empty list, which gives us (l_{b1},l_{b2}) as the final result.

As discussed earlier, the queue mechanism has to be used as

an intermediate storage process to ensure that none of the

retrieved lists will be lost. By means of parameterization

all the operators described in the mathematical part of the

specification (spec property_id through spec database) can be

applied using the adequate list operations. This is achieved

by short hybrid specifications (spec pidlist through spec

dblist) which combine the parameters defined in 'spec list'

with the corresponding operators of the original specifications,

giving access to all the operations of data type 'lst.'

D.   THE LIST STRUCTURE APPLIED TO DATABASE DESIGN

In this section we describe how the application of the list

theory supports the fundamental database operations. Since

the structure of the abstract database can be compared with a

large list, this concept will be discussed in more detail.

Starting with the basic elements 'property_id' and 'value,'

each of the related data types may be considered as forming a

119

list containing just the single element <pid> or <val>, while their sets are represented by lists consisting of as many sub-lists as required, for example,

<<pid1>,<pid2>> or <<val1>,<val2>,<val3>>.

Consequently, a 'property' which is defined by a 'pid' and a 'valset' can be expressed by means of a list containing these two major sublists as elements, where the second list is itself composed of a number of single lists:

< <pid>,< <val1>,<val2>,...,<valn> > >.

Adding another '<' at the beginning and one '>' at the end combines several properties into a 'propertyset.' Applying this technique to 'propertyvalue' which represents an instance of a property, the resultant looks like the following:

< <pid>,<val> >

and the corresponding set can be created by combining the necessary number of adequate ordered pairs

< < <pid1>,<val1> >,< <pid2>,<val2> >,...,< <pidi>, vali

To construct an 'object' is now straightforward since the object is nothing more than a particular 'propertyvalueset' itself. The 'objectclass' then can be considered as a number of different objects put into the same list. But caution has to be taken that we do not violate our definition of a class. Since objects can only be grouped together if they are structured in a similar way, it is mandatory that they contain exactly the same number of corresponding 'pids.'

120

A 'class' can be expressed by a list of the form:

$$< \ < \ < \ <pid1>,<val11> \ >,\ldots,< \ <pidi>,<vali1> \ > \ >,$$
$$< \ < \ <pid1>,<val12> \ >,\ldots,< \ <pidi>,<vali2> \ > \ >,$$

$$\vdots \qquad \vdots \qquad \vdots\vdots\vdots \qquad \vdots \qquad \vdots$$

$$< \ < \ <pid1>,<val1j> \ >,\ldots,< \ <pidi>,<valij> \ > \ > \ >;$$

where the kind and number of 'pids' is the only criterion for
associating a given object to a certain class, while any 'value'
necessary for describing an object can legally be attached to
a 'pid' as long as it is defined in the appropriate domain.

Finally, the database can be treated like a big list con-
taining several lists of the class type just described, where
the same criteria must be met on a higher level. To see how
an operation on this list structure works, let's consider the
disjoint operator for 'pidsets':

$$\text{intpidset}(\text{pidset1},\text{pidset2}) \ --> \ \text{pidset3};$$

where, for example,

$$\text{pidset1} = \ < \ <pid1>,<pid2> \ >;$$
$$\text{pidset2} = \ < \ <pid1>,<pid3> \ >.$$

Invoking the parameterized spec pidsetlist gives us access to
both spec list and spec property_idset. 'Intpidset' is then
replaced by 'intlst' which by substitution leads to the
operation

$$\text{intlst}(< \ <pid1>,<pid2> \ >,< \ <pid1>,<pid3> \ >).$$

Since operator 'intlst' is handled by the recursive axiom

121

```
        if or(
            (eqlst(ll,nullst()) = true()),
            (eqlst(l2,nullst()) = true())
          ) = true()
        then
            intlstIfirstlst(ll),l2) = nullst();
        else if memblst(firstlst(ll),l2) = true()
        then
            catlst(firstlst(ll),intlst(restlst(ll),l2));
        endif;
```

first the termination condition is checked, which means, if
either of the two lists is empty then the intersection must
be equal to the null-list ('if-then' part). In our particular
case they are not empty, so the 'else-if' part will be tested.
Since the first list ('<pidl>') of ll ('<<pidl>,<pid2>>') is
contained in l2 ('<<pidl>,<pid3>>'), this condition holds and
the concatenated list ('catlst[<pidl>,intlst((<pid2>),(<pidl>,
<pid3>))]') is created where 'intlst' invokes a recursive opera-
tion on the rest of ll ('<pid2>') and l2 ('<pidl>,<pid3>').
This time, since neither the 'if' nor the 'else-if' part is
true, the 'else' condition is applied which leads to a repeated
operation on the rest of ll and on l2:

        intlst[<>,(<pidl>,<pid3>)].

Now the 'if' part of the axiom becomes true which returns the
empty list. This results in the concatenation

        catlst(<pidl>,<>)

and gives '<pidl>' as the intersection of ll with l2.

E. LIST RETRIEVAL

In the previous sections we developed the abstractions of
the database resource and discussed the set of operators that
apply to database programming. In AM (version 2.0) the 'state'
of the machine consists of the aggregation of the memory,
register, stack cell contents, display register and monitor.
We will now extend the 'state' to include the new entity 'queue.'

1. Background on the Processor Resource

For a better understanding of the applied extension,
in the following paragraph a brief description of AM, taken
from Hunter [Ref. 3], will be presented.

In AM (version 1.0) the five primitive data types,
boolean, natural, integer, character, and string, form the
atomic data types and are referred to as 'atoms.' Yurchak
[Ref. 2] as the implementor of AM discussed the impact of the
relationship between the data and a conventional machine on
portability issues in detail, and identified the following
properties of AM which were used to reduce the "semantic gap"
and give AM its uniqueness:

- in the organization of primary storage, the next
  logical data item is in the next logical address;

- except as formally specified, no data type may be
  accessed in any way, as another data type;

- given any arbitrary logical address, the value stored
  there and its type can always be determined.

The processor portion of AM is an abstraction of a conventional
"Von Neumann" machine with some unconventional properties.
The only machine element is called a 'value.' All data

123

primitives (atoms) map into values. Spec typing, as introduced
by Hunter, describes the relationship of 'values' and 'atoms.'
As an illustration of this relationship consider the inter-
sect operation on two 'pidsets.' We fetch the value represen-
tation of the first 'pid' of each set from two registers, and
convert each value to its 'pidset' atom with the 'atomofpidset'
operator. The 'pids' are intersected in accordance with the
'pidset' data type, and the resulting 'pid' is converted back
into a value with 'valofpidset' for storage into a register.
The operation will be continued recursively until both 'pidsets'
are completely intersected.

Primary storage is an array of one or more memory seg-
ments, each of which may contain an arbitrary number of cells.
Each cell is capable of "containing" any legal data value.
Both programs and data may reside together in a single segment.
For high speed storage, there are one or more register seg-
ments, each of which contains an arbitrary number of registers.
AM also has one or more stacks, a heap, a crude file system,
and now a queue. Again, every register, stack and queue cell
is capable of containing any type of data.

The basic atomic data types are augmented by several
others needed for the execution of programs. These are in-
structions and memory, register, stack, file addresses, and
the queue.

2. The Queue

The value representation of the new data types 'pid,'
'pidset,' 'val,' 'valset,' 'prop,' 'propset,' 'pval,' 'pvalset,'

124

'obj,' 'class,'and 'db,' may be placed in any memory, register,
or stack cells with one exception: whenever a set of 'pids,'
'vals,' 'pvals' or 'objs' will be retrieved, they can not be
displayed until they are first placed in the queue. The con-
cept of the queue is similar to a stack. Since we do not want
the programmer to have access to the "inside" of the queue nor
want to provide facilities for altering the queue in any way,
we make its use only available for the very special purpose
of acting as a buffer for the data retrieved from the database
so it can be returned to the programmer when a search is com-
plete. The reason for introducing the queue is that the order
always matters in a database. Thus, a stack which reverses the
sequence between inputs and outputs would not work for this
case. The queue preserves the order in which data is entered,
and although queue operations are more difficult to specify
than the stack operations, it finally was adopted.

To make the queue mechanism operational in a similar
way as the stack, instructions were installed for opening/
closing and reading/writing ('spec instructions'), while the
operations for defining the state of the queue and their meaning
were added to 'spec amstate.' The program portion is described
in 'spec am' which makes the queue an integrated part of AM.

The database resource can be invoked by the operator
'opendb' which requires a characterstring as identifier, a
database, a state, and returns a state. Provision for closing

125

the database is made by the operator 'closedb' which requires

a database and a state as input and returns a state, thereby

terminating the access.

VI.   IMPLEMENTATION

At present, only the original AM, version 1.0, is imple-
mented and operates as a finite state machine interpreter. It
comprises approximately 12,000 lines of C code, including the
assembler. Developed by Yurchak, the overall concept for the
assembler is as simple as it is effective. A text file repre-
senting an assembly language program is translated by the
assembler into a relocatable object module. A loader, part of
the AM interpreter, then loads this object module into the
appropriate cells, and AM executes it. The reader is referred
to Appendix C for more details about the assembler.

Since Yurchak [Ref. 2] as the originator provides a complete
description of the AM implementation, we will repeat major
portions of his work but also consider points of interest found
in Hunter's [Ref.3] description of the version 2.0 extension
while finally adding s me examples and discussion of our latest
modification towards AM, version 3.0.

For time reasons, neither the bit-mapped display nor the
database resource have actually been implemented. Rehosting the
original AM, version 1.0-Unix from a VAX 780 to a Zenith Z100
microcomputer by Hunter manifested once again all the typical
difficulties known as "the portability problem." This rehost-
ing required approximately 350 functions to be renamed
throughout the 12,000 lines of code, since the compiler and

127

linker now used operate on shorter character names only.
Another problem Hunter faced during the re-implementation of
version 1.0 was that, although the Unix C compiler allowed
passing of structures by value, the Lattice C compiler for the
Zenith version does not, so the entire program had to be
converted to passing structures by pointer. Thus major parts
of the initial AM had to be modified or rewritten by Hunter.

But despite these problems usually encountered when porting
software, the number of test programs developed for the Unix
version run on the Zenith Z100 with the same results. So far
the assembler has been revised to handle the full extension
for both versions 2.0 and 3.0, including all new data types,
the resource extensions, plus some additional operators for the
original data types, as mentioned before. The machine itself
however, has not yet been extended to handle the new data types
introduced by the gradual modification. This remains for
some future work.

After this description of the present state of the AM
development, we will now continue with the overview of the
implementation. There are four main areas: the representation
of data types, the mapping of operators in the specification to
functions in the interpreter, the handling of errors, and
the execution of a program.

A. IMPLEMENTING DATA TYPES

Since it provided an easy translation from the specifica-
tion, C was adopted by Yurchak as the corresponding programming

128

language for AM. But as he states in his work, another
language, like LISP might have done the job as well.

AM is a tagged architecture. Each data element or value
must be self-descriptive. As Hunter points out, it is impor-
tant to realize the distinction between an atom which corres-
ponds with a data type, and a value. In contrast to an atom
that is referred to as sort in our specifications and repre-
sents a problem solving abstraction like 'pid' or 'obj' for
the database, a value embodies a machine element. Furthermore,
an atom is representation independent and keeps its level of
abstraction, while a value is the specific representation of
such an atom. Representation independence is achieved by cer-
tain conversion functions (Appendix B) that map all atoms into
appropriate values and vice versa. This translation technique
enables us to determine the type of a value solely from the
value itself, which is one of the distinct properties of AM
and gives the machine its tagged architecture, introduced to
ease the "portability problem." The most likely construct to
provide this feature is a structure (record).

Each atom is represented in C-language as a structure con-
sisting of a 16-bit tag field, and a value field. The size of
the value field varies with the type. Each sort in the speci-
fication, as the equivalent to an atom, is assigned a 16-bit
code. Whenever an atom is created, or copied, it is tagged
with the appropriate code. Figure VI.1 lists some fragments
from the header files used by our interpreter and represents

129

the 'natural' data type which has a simple value field.
Hunter [Ref. 3] compressed the initial term 'NAT_TYPE' to the
handier 'T_NAT' for the reasons given above.

```
#define T_NAT     0x0002        /*natural type tag*/
typedef unsigned intnat;

typedef struct {
     short type;
     nat   val;
} NAT;
```

Figure VI.1. Type Definitions for Natural

By using a fixed size tag field as the first field in each
record, we build in some additional robustness since, even
in the event of a mistyped structure being copied into the
formal parameter of a function, we can rely upon the first
word to be a valid code (the type).

The next step is to describe the structure for machine
values that must be capable of containing any atom. To manage
this problem, Yurchak introduced the union operation which
involves every single sort defined in the specifications so
that any atom can be represented by the value structure. Due
to the "Z100" characteristics, the value structure is divided
into portions of two bytes for the tag field and four bytes
for a pointer; the data type's value will be represented
either directly in such a value field or, if it can not be
expressed within the space of the four bytes available,

130

a pointer to its real location is used. String and list structures are examples that use pointers since their size is variable and usually large.

Figure VI.2 shows the concept of the union structure for machine values VAL. Because the number of data types increased very much in the latest modification of AM, only a sample of the values actually present is given. Hunter [Ref. 3] also notices that INSTR itself represents a VAL pointing to another VAL which contains the instruction's opcode. By this technique it becomes possible to fetch and store instructions, thereby allowing us to put a program into memory and to execute it.

The primary physical resources are also defined as structures. A sample of these resources is presented in Figure VI.3. Registers, display registers, memory and stacks are represented as arrays of arrays of pointers to values. The reader should note that a simple change to the constants in the header files can completely alter the configuration of the machine. We can specify an arbitrary number of arbitrary long memory, register and display register segments, as well as different sizes for an arbitrary number of stacks and the queue. Database and file are represented as an array of structures, with the files containing an input/output buffer in addition to the status information contained in both. The number of separate databases or the number and type of files can be changed by recompiling the corresponding module of the interpreter.

```c
typedef short opcode;

typedef struct {
      short type;
      union value *val;
} INSTR

typedef union value {
      short    type;
      opcode   opcdval;        /*this is the compressed version
                                 of the initially used term
                                 'opcodeval'*/

      BOOL     boolval;        /*starting here the data types
      INT      intval;          are listed*/

       .        .
       .        .
       .        .

      FONT     fontval;
      LIST     listval;

       .        .
       .        .
       .        .

      MAD      madval;         /*memory address*/
      QADDR    qaddrval;       /*queue address*/

       .        .
       .        .
       .        .

      INSTR    instrval;
      MOP      mopval;         /*monadic operator*/
      DOP      dopval;         /*dyadic operator*/
} VAL;
```

Figure VI.2.   Machine Values

```
typedef struct {                          /*memory segment*/
     int   size;
     VAL  **val;
} memseg;

typedef struct {                          /*stack segment*/
     int   size;
     int sp;
     VAL   **val;
} stkseg;

typedef struct {                          /*queue segment*/
     int   size;
     VAL  **val;
} qseg;

typedef struct {                          /*file segment*/
     int   stat;
     int   mode;
     int   type;
     int   val;
} fileseg;

typedef struct {                          /*database segment*/
     int   stat;
     int   val;
} dbseg;

#define_NUMMEMSEG    1024
#define_NUMSTKSEG       1
#define_NUMQSEG         1
#define_NUMFILES       16
#define_NUMDB           1                 /*defined for 1 database*/

memseg_mem[_NUMMEMSEG] = {
     1024,0
     1024,0 } ;
stkseg_stk[_NUMSTKSEG] = {
     512,512,0 } ;
qseg_q[_NUMQSEG] = {
     512,512,0 } ;
```

Figure VI.3.   The Physical Resource

With respect to the characteristic requirements for retrieving selected contents from the database, the queue was provided to act as a buffer. Since this is the primary reason for the queue, its accessibility has been limited to serve just this purpose. There are in fact only three ways of accessing the queue, either directly or via main memory and register operations that directly lead to the physical address of the data. The database must be opened similar to a file in order to perform the desired operations, and must be closed again when the operations are terminated.

B. MAPPING OPERATORS TO FUNCTIONS

It seems natural, although incorrect, to look at the operators in a spec as functions. However, in the implementation, this makes perfect sense. Figure VI.4 lists the code for the AM module which implements the boolean type. The header files which provide the constant definitions are omitted here. Notice that, where possible, we rely upon the operations provided by the C language, rather than slow down an already slow interpreter with axiomatic implementations of the operators.

As the implementation proceeds to more complex specifications, the program relies less upon C and more upon the operators which we have defined. In fact, the more complex operators are implemented as calls to previously defined functions which almost directly mimic the axioms from which they are derived.

134

```
BOOLtrue = { T_BOOL,1 };                    /*the initially used BOOL_
                                             TYPE was replaced by the
                                             more complex term T_BOOL*/
BOOLfalse { T_BOOL,0 };
BOOL *not(a)
BOOL a;
{
  BOOL *tmp;                                 /*'tmp' was installed by
                                             Hunter*/
  tmp = (BOOL*)tmalloc(sizeof(BOOL));
  tmp->type = T_BOOL;
  tmp->val!= a->val;
  return(tmp);
}

BOOL *and(a,b)
BOOL *a,*b;
{
  BOOL *tmp;

  tmp = (BOOL*)tmalloc(sizeof(BOOL));
  tmp->type = T_BOOL;
  tmp->val = (a->val&&b->val);
  return(tmp);
}

BOOL *eqbool(a,b)
BOOL *a,*b;
{
  BOOL *tmp;

  tmp = (BOOL*)tmalloc(sizeof(BOOL));
  tmp->type = T_BOOL;
  tmp->val = (a->val ==  b->val);
  return(tmp);
}

BOOL  *nebool(a,b)
BOOL  *a,*b;
{
  BOOL  *tmp;

  tmp = (BOOL*)tmalloc(sizeof(BOOL));
  tmp->type = T_BOOL;
  tmp->val = (a->val !=  b->val);
  return(tmp);
}

BOOL  *or(a,b)
BOOL  *a,*b;
{
  BOOL *tmp;
```

Figure VI.4   Operator to Function Mapping for Type BOOL

135

```
tmp = (BOOL*)tmalloc(sizeof(BOOL));
tmp->type = T_BOOL;
tmp->val = (a->val | b->val);
return(tmp);
}
```

Figure VI.4 (CONTINUED)

C. ERROR HANDLING

The method of treating errors was entirely revised by
Hunter. All errors in the specifications are now described with
the 'undef' operator. By definition, that makes all errors
fatal, but they need not be. Those errors which are not, must
then be defined explicitly in the specification. As remarked
earlier, a more detailed treatment of errors would be an area
for further study.

AM flags most errors in the operators which perform data
conversions. This is a natural place for this to occur, since
it is difficult to see how the type of a data element may be
changed at any other time. Figure VI.5 shows a fragment which
implements the 'property_id' conversion routines. The routine
'error' does not return, but terminates execution after writing
the error message to 'stderr.' Notice that, even if a much
larger structure was passed to 'atomofpid' or 'valofpid,' the
error would be detected and handled gracefully.

This type of error checking is also performed in the func-
tions which implement data operations.

136

```
PID   *atpid(v)                        /*short form for atomofpid*/
VAL   *v;
{
  PID   *b;

  if(v->type != V_PID)                 /*reduced term for PID_VAL*/
        error("value not of type PID -%x", v->type);
  b = (PID*)tmalloc(sizeof(PID));
  b->type = T_PID;                     /*reduced term for PID_TYPE*/
  b->val = v->pidval.val;
  return(b);
}
VAL   *vlpid(b)                        /*short form for valofpid*/
PID   *b;
{
  VAL   *v;

  if(b->type != T_PID)
        error("atom not of type PID -%x", b->type);
  v = (VAL*)tmalloc(sizeof(VAL));
  v->pidval.type = V_PID;
  v->pidval.val = b->val;
  return(v);
}
```

Figure VI.5.   Error Handling Routine for Property_id Type

D.   EXECUTION

The final point of interest involves actually executing a

program.   The method is also illustrative of the way in which

the program mimics the axioms of the specification.   Here,

too, we resort to subterfuge to implement in a finite way a

specification which could require the expenditure of an infinite

resource (an implied stack in this case).   The problem is the

corecursive relationship between the functions 'xeq' and

'prog.'   We eliminate this problem by never actually returning

from 'xeq.'   We rely on a dangerous but effective C idiom,

'setjmp' and 'longjmp.'   Figure VI.6 illustrates this.

```
main(argc,argv)
char *argv[];
{
    int ap;                          /*check for toggles*/
    for (ap=1;ap<argc;ap++){
        if (*argv[ap] == '-'){
            if (*(argv[ap]+1) == 'x'){
                traceflag = 1;       /*added by Hunter*/   .
                xtraceflag = 1;
            }
            if (*(argv[ap]+1) ==  't')
                traceflag = 1;
        }
    }

    initiam();                       /*main body*/
    amload();
    setjmp(_context);
    Q = prog(&_pc,Q);
    exit(0);
}

STATE    prog(m,q)                   /*program for prog*/
MAD *m;
STATE    q;

    q = xeq(atinstr(fetchm(m,q)),m,q);
                                     /*short term for atomofinstr*/
}

STATE    xeq(i,m,q)                  /*program for xeq*/
INSTR *i;
MAD *m;
STATE    q;
{
    opnd *p;
    if (i->type!=T_INSTR)            /*short term for INSTR_TYPE*/
        error("attempt to execute non-instruction -%x", i->type);
    p = i->val;
    switch(getopcode(p[0].opcodeval)){
    /*a case and semantics for each valid opcode goes
     here*/
    default:
    error("attempt to execute an illegal instruction -%x",
        p[0].opcodeval);
    }
    longjmp(_context,1);
}
```

Figure VI.6.   Program Execution

In 'main,' 'initam' configures AM and invokes all of the initialization operators. 'Amload' loads a program from secondary storage into the appropriate cells as directed by the linker directives in the object module. 'Setjmp' then saves the state of the "real" machine. The variable '_pc' is the program counter which is set inside 'amload.' Now everything is set. The program is loaded and ready to run.

'Prog' is now called. Notice that 'prog' simply invokes 'xeq.' Recall now the axiom which defines the semantics of execution:

$$prog(m,q) = xeq(atomofinstr(fetchm(m,q)),m,q);$$

The value of a language which permits usefully long names is obvious in this case. Within 'xeq' a large case statement decodes the instruction and executes it according to the semantics provided for that case. This semantics is very closely modeled on the axioms in the specification. Figure VI.7 shows one such case and its accompnaying semantic action.

```
case IM_M_M;
  q = storem(
        fetchm(
          &p[1].madval,          /*val of memaddr pointed to
                                    by p[1]*/
          q                      /*q:state*/
        ),
        &p[2].madval,
        q
  );
  _pc.val = nxtmad(m)->val;
  break
```

Figure VI.7. The Semantics for 'mov_m_m'

Now compare Figure VI.7 to the axiom for mov_m_m.

```
xeq(mov_m_m(m1,m2),m,q) =
     prog(
          nxtmad(m),
          storem(
                 fetchm(m1,q),
                 m2,
                 q
          )
     );
```

The similarities are not accidental. This should make the
point that it is beneficial for the implementation language
to permit such a close modeling of the specification. Obviously,
this made the implementation easier to write, debug and
understand.

E.   DATABASE IMPLEMENTATION ISSUES

Similar to a file system, the database consists of two
major parts: the information contained in it and the program
that allows the user to manipulate this implementation. Once
implemented, both program and content of the databases are
rather fixed, although the information part can gradually be
changed by iterated application of the appropriate commands.
Thus in general the user is limited to retrieving or modifying
the stored information, but this is the main purpose of a data-
base. Should a conceptual change of the contents become neces-
sary after a while, it is more convenient to revise the kind
and arrangement of the data, and let the entire database then
be re-implemented by an application programmer.

Theoretically, there exist no boundaries for the size of our abstract database, which means objects can be defined by any number of propertyvalues, and classes may contain any number of objects. But in reality we cannot ignore the capability of the available physical resources. Since databases tend to increase rapidly, the capacity of the attached storage device will set the natural limit.

Practically speaking, a user would need a DDL tool to effectively create a database, just as a compiler would be needed to effectively write programs for AM. The purpose of this thesis however, is to give a precise specification of the low level resources needed for a database.

The particular commands accessible by the user will be fully integrated into the AM instruction set. They mainly consist of the operations described in spec objectclass and spec database and are considered sufficient to perform all the necessary data manipulations. The operators provided permit the insertion and deletion of an object into/from a given class, the update of an object by modification of its contents, and the selection of one or more objects in accordance with a predefined condition. As soon as the database part of AM is invoked (instruction 'opendb') these commands can be applied to the contents representing this database after they are brought into main memory first. For any change, data are fetched from their memory location, loaded into a register, and stored back when the operation is completed. After

141

termination of the desired activities the database must be closed (instruction 'closedb') and the data will be transferred back to secondary storage. This procedure ensures that the data residing in secondary storage at the end of the operation always represent the actual state of the database. A presorting of data outside main memory is not feasible, since we do not presume the existence of an additional processor which is usually known as back-end computer.

To select an object on the basis of a certain entity by which it is defined, called 'propertyvalue' ('pv') in our terminology, the characterizing 'pv' will be loaded into a register as a comparand. Identified by the corresponding 'property_id' of this 'pv,' the class possibly containing the required object is then localized and the entire 'pv' set of its first object will be loaded into a separate set of registers. If a match occurs between the comparand and the register containing the adequate 'pv' of the object, the total 'pv' set is copied into the queue and the next object will be loaded. If no match takes place the procedure will be continued without storing the object in the queue. When the entire class has been searched, the 'select' operation terminates and the resultant object(s) can be read from the queue. The state of the database will not be changed by this operation since only a partial copy is taken. But it can not be excluded that none of the objects would meet the criterion searched for. In this case no copy will reside in the queue and the returned 'pv' set is empty.

In contrast to the 'select' operation, which can be considered as a read function, insertion, deletion, and modification actually do change the given state of the database, so these operations are a little more complicated. Inserting a new object requires, besides the 'pv' set that defines it, the class to which it is inserted. This technique ensures that no object accidentally will be inserted which is not attached to a certain class. Without this restriction, the structure of the database could be changed in an unacceptable way. When the class has been identified by comparison of the corresponding 'property_ids' the new object will be added at the end of that class. An error handling routine is invoked should the required class not exist.

At this point the question must be answered where the special identifier or 'key,' mentioned in a previous chapter, would best fit. Such a device is necessary to distinguish between 'pv' sets which incidentally are identical, although they may represent different objects, or to detect an unwanted redundancy. Only an identifier that is unique to every single object can meet this requirement. However, the simple arrangement of the objects in a numerical order would not work, since by mistake the same object could be listed under different numbers without the means of recognizing the error. The only way to solve this problem is by introducing a key value that can only be applied in connection with the particular object it defines, like a social security number or a similar characteristic

143

attribute. We adopt this technique but leave the selection
of the proper criterion up to the application programmer.
However, it is considered advantageous always to define the
first 'property_id' of a class as the key element. This would
allow the arrangement of the objects in a numerical or alpha-
betical order with regard to their identifiers.

Deletion and modification have one thing in common. The
particular object must be retrieved first before the operation
can be applied. This will be achieved in a similar way as for
the 'selection' operator. The 'pv' set of the object in ques-
tion is loaded into a set of registers and the appropriate
class is identified. Then the 'pv' set representing the first
object of the class is loaded into a separate set of registers
and checked for identity. As soon as a match occurs the search
stops. In the case of a modification the up-dated 'pv' set
will be stored in memory and the pointers are adapted to the
new location. For a deletion operation the pointers are advanced
and the "erased" object will be by-passed. If the indicated ob-
ject cannot be found in the appropriate class, an error handling
routine is activated and the state of the database will not
be changed.

VII. CONCLUSIONS

Interface standards that are precise, understandable and enforceable can provide a way to improve efforts toward portable software. With the abstraction of a database, we not only extended AM by adding another basic resource to the processor and the visual display device, but also showed a way to reduce the database to its fundamental properties. Rather than being concerned with a specific data definition or query language, our abstraction of a database is intended to provide a uniform, abstract, and functional interface to the computing system.

By this concept the application programmer retains all the freedom he needs to actually implement the database resource in a way that fits his purpose best. And although it may turn out that the AM machine becomes even slower as the result of the additional data types we introduced, the specified axioms fully describe the operations in a precise, unambiguous and easily understandable manner, thus leaving no room for any different interpretation by the programmer.

Based on the principle of resource abstraction, the AM specification intensively supports a strong typing such that objects of a given type can not take other values than the ones appropriate to the type, and no operations can legally be applied to an object which are not defined for its type. All these decisions naturally reduce efficiency, but this loss will be compensated by gains in clearness and accuracy.

145

It is difficult to foresee how much AM can be modified for efficiency without compromising the level of abstraction presently achieved. To test for resource equivalence or to prove the correctness of implementations of resource specifications is a nontrivial matter, and this problem certainly will increase with every change attempted. So, for the near future, it seems that we have to pay the price for implementing in a strictly formal way, since no promising theory is yet known to reduce the large number of necessary function calls within the specification.

Further basic resources that could be taken into consideration for a possible AM extension are a so-called mouse device with properties similar to the joy stick cursor, and a keyboard.

            ),
            pushstk(valofmemaddr(nextmemaddr(m)),s,q)
        );
    xeq(rts s,m,q)=
        prog(atmoofmemaddr(topstk(s,q)),popstk(s,q));
    xeq(open(s),m,q)=
        prog(
```

267

```
                nextmemaddr(m),
                openfile(
                    atomofstr,char(topstk(s,popstk(s,popstk
                        (s,popstk(s,q)) )) ),
                    atomoffile(topstk(s,popstk(s,popstk(s,q)) )),
                    atomofint(topstk(s,popstk(s,q)) ),
                    atomofint(topstk(s,q)),
                    popstk(s,q)
                )
            );
    xeq(close(s),m,q)=
        prog(
            nextmemaddr(m),
            closefile(
                atomoffile(topstk(s,q)),
                popstk(s,q)
            )
        );
    xeq(read(s),m,q)=
        prog(
            nextmemaddr(m),
            storem(
                infile(
                    atomoffile(topstk(s,popstk(s,q)) ),
                    popstk(s,q)
                ),
                atomofmemaddr(topstk(s,q)),
                popstk(s,q)
            )
        );
    xeq(write(s),m,q)=
        prog(
            nextmemaddr(m),
            outfile(
                fetchm(
                    atomofmemaddr(topstk(s,popstk(s,q)) ),
                    popstk(s,q)
                ),
                atomoffile(topstk(s,q)),
                popstk(s,q)
            )
        );
    xeq(write_i(v,qu),m,q)=            /* database part */
        prog(nextmemaddr(m),write(v,qu,q));
    xeq(write_m(ml,qu),m,q)=
        prog(nextmemaddr(m),write(fetchm(ml,q),qu,q));
    xeq(write_r(r,qu),m,q)=
        prog(nextmemaddr(m),write(fetchr(r,q),qu,q));
    xeq(delete_x(qu),m,q)=
        prog(nextmemaddr(m),delete(qu,q));
```

268

```
            xeq(delete_m(qu,ml),m,q)=
                prog(
                    nextmemaddr(m),
                    delete(
                            qu,
                            storem(
                                    read(qu,q),
                                    ml,
                                    q
                            )
                );   )
            xeq(delete_r(qu,r),m,q)=
                prog(
                    nextmemaddr(m),
                    delete(
                            qu,
                            storer(
                                    read(qu,q),
                                    r,
                                    q
                            )
                    )
                );
            xeq(open(s),m,q)=
                prog(
                    nextmemaddr(m),
                    open(
                        atomofstr.char(vl),
                        atomofdb(v2)
                    )
                );
            xeq(close(s),m,q)=
                prog(
                    nextmemaddr(m),
                    close(
                        atomofstr.char(vl),
                        atomofdb(v2)
                    )
                );                              /* database part */
        end extend;
    end am;
```

APPENDIX C

A SIMPLE ASSEMBLER FOR AM

1. Introduction

This document is adapted from Yurchak [Ref. 2], Appendix
C, and constitutes the reference manual for both version 2.0-
Z100, developed by Hunter [Ref. 3], and the latest modification
towards version 3.0. It provides a comprehensive description
of the syntax and semantics of the assembler as well as a
description of the salient features of the AM machine and a
definition of the opcodes executed by AM.

AMASM is an assembler which generates a relocatable load
module for the abstract machine interpreter AM. It is to the
extent possible written in portable C. The parser and scanner
were produced using the Unix YACC and LEX utilities. The
output from these utilities require several patches to allow
compilation on the Z100 using Lattice 'C.' Readers desiring
to port the code to other machines may have to make slight
changes to "defines." In this implementation, longs are
assumed to occupy 32 bits, both int and short - 16 bits, and
char - 8 unsigned bits. NOte: if the int size changes, then
the infile and outfile functions in amstate.c must be changed.

The input syntax of AMASM is similar to that of other
assemblers. It supports symbolic addresses and constants and
a typical set of directives, but has no macro capabilities.
The assembler accepts an ASCII source file created on a con-
ventional text editor and produces an output file containing
relocation information and AM opcodes. Invoking AM causes the
output file "a.am" to be loaded and executed.

2. Differences from Version 1.0

Since it was our intention to primarily specify and des-
cribe the abstraction of a database resource, the assembler
part for AM was considered to be of less importance for this
thesis. Due to the limited time the adaption of AMASM to the
database requirements is still incomplete, only some examples
are given which indicate a way of how to integrate this latest
resource. Thus, for instance, although the read/write com-
mands for the queue were developed, the method of actually
retrieving objects from the queue has not yet been defined.
The same is true for the database itself, where the only
commands described are those for opening and closing the

270

database, while the other operations were left undefined for the above reasons. So, in fact, AM (version 3.0) represents only a partial extension of AM (version 2.0-Z100).

3. Usage

AMASM is invoked with the following command line syntax:

amasm [-t][-x][-s][-l] file ...

AMASM produces a single load module "a.am," which forms the input to the AM loader. The optional "-t" switch sends a debugging trace to "stdout," the "-x" switch provides an extended version of the trace, and the "-s" switch provides trace of the recognized scanner tokens. The optional "-l" switch generates the listing and cross-reference file "a.x." Appended to this file is a hex dump of "a.am."

4. Lexical Conventions

Assembler tokens include identifiers (alternatively, "symbols" or "names"), literal constants, operators and delimiters.

4.1. Identifiers

Legal identifiers are described by the following regular expression:

[A-Za-z][A-Za-z0-9]*

Identifiers consist of a letter or underline "_" followed by a string of zero or more letters, decimal digits and underlines. Upper and lower case are distinct. Identifiers may represent symbolic constants, instruction mnemonics, labels, addresses and type names.

4.2. Operators

The following are considered to be operators:

== != < <= > >=

+ - * / % & |

The meaning of the above symbols varies with context.

4.3. Literal Constants

Decimal and hexadecimal constants are described by the following regular expressions respectively:

[-+][0-9]+| [0-9]+
$[0-9A-Fa-f]+

271

Decimal constants consist of an optional sign followed immediately by one or more decimal digits. Hexadecimal constants consist of the character "$" followed immediately by a string of one or more decimal digits and upper or lower case letters "A"through "F." Numeric constants may represent addresses, integer and natural numbers, boolean and character values.

Character constants consist of a single quote " ' ", followed either by an ASCII character, that is not a carriage return/ linefeed or a numeric constant, followed by a closing single quote.

String constants consist of a string of zero or more ASCII characters (except carriage return/linefeed) enclosed in double quotes.

4.4. Blanks

Blanks and tabs are ignored by the assembler except where required to separate adjacent constants or identifiers.

4.5. Comments

The character ";" produces a comment. The assembler ignores all further characters on the line up to the terminating carriage return/linefeed.

4.6. Delimiters

All other characters found in the input stream are treated as delimiters.

5. Statements

A source program is composed of a sequence of statements, one statement per line. There are 3 kinds of statements: directives, instructions and null.

Instructions and null statements may be preceded by a label. Directives may (in some cases, must) be preceded by an identifier.

5.1. Labels & Identifiers

A label consists of an identifier followed by a colon ":". When the assembler encounters a label, the effect is to assign the current value of the location counter to the name.

An identifier preceding a directive is assigned a value whose type depends upon the directive. For instance, the equate

directive assigns a typed value to an identifier, while the
define storage directive assigns the current value of the
location counter.

Neither labels nor identifiers may be redefined within
a single source file.

5.2. Null Statements

A null statement is an empty statement. Although ignored
the assembler, null statements may be preceded by a label.

5.3. Directive Statements

A directive is a command to the assembler to perform some
sort of operation which does not involve emitting an executable
instruction. Typical directives (also known as "pseudo ops"
or "pseudo instructions") allocate storage for variables, make
names within the current module visible to other modules and
set the location counter. Directives also produce instructions
for the AM linker and loader.

Directives consist of a keyword followed by zero or more
arguments, depending upon the context. Directives and their
syntax are described in more detail in Section 12.

5.4. Instruction Statements

Instruction statements produce the code which is ultimately
executed by AM. An instruction may be preceded by a label,
and consists of a keyword followed by zero or more arguments,
depending upon context.

The AM instruction set and its syntax will be described in
detail in Section 14.

6. The Machine

Because AM differs from conventional machines in a number
of important ways, some discussion is necessary before intro-
ducing the instruction set. Outwardly similar to a number of
well-known examples, AM instructions form an unconventional
set of primitive operations which implement a formally speci-
fied semantics. The reasons for this are described below.

AM uses a tagged architecture. Thus, each data element
contains, within it, information which uniquely identifies a
finite set of legal operations which may be performed upon it,
as well as a range of legal values it may take on. This set
of operations and values is known formally as a data type.
AM supports a number of data types. An element of a particular
data type will be referred to throughout the rest of this manual
as an atom.

273

AM physical resources are partitioned into segments. There
are several types of segments, and these together form a con-
ventional overall model of the familiar stored program computer.
There are memory segments (primary storage), register seg-
ments (high-speed memory), display register segments (bit-
mapped display memory), stacks, a queue, a monitor (display
terminal attributes) and file segments (secondary storage).
Segments are further partitioned into discrete, addressable
elements (alternatively, "cells") which will contain atoms
during the execution of a program. These elements will be
referred to repeatedly as typed values. The reason for the
distinction between atoms and values will become more clear
shortly.

AM is the finite implementation of a formal specification.
As such, data elements and the operations which can be applied
to them must reflect a mathematical consistency not required
by conventional architectures. Since all operations which
affect the state of the machine must be able to "communicate"
with each other during the execution of a AM program, they must
do so using a common object. This object is a value. The
memory, registers, display registers, stack, queue, and files
all hold values. Store, fetch, execute, read, write--any
operations which change the state of the machine--all operate
on values (i.e.,storage cells). All other operations, such as
"add," "multiply", "and," and "or," work on atoms. Atomic
operations in AM correspond to those which take place in the
temporary registers of the arithmetic and logic unit of a con-
ventional processor.

6.1 Configuration

A unique feature of AM is the ease with which it is possible
to reconfigure the machine by partitioning the physical resources
in different ways. A typical configuration would be something
like this:

    2 memory segments
    1 register segment (with a useful number of registers)
    1 display register segment (with one or two registers)
    1 stack
    1 queue
    1 monitor (only one is permitted)
    1 database (one or more are possible)
    16 files

The configuration chosen should provide a good indication of
the types of programs AM is intended to execute.

Note that, in conventional machines, stacks are implemented
in primary storage. This constitutes an overloading of data
structures which obscures the intent of the user of these
structures. It also creates a semantic nightmare for the

274

specification writer. In AM, stacks and queue take their rightful places as separate entities with easy to understand properties.

In addition to the resources listed above, AM has a conventional program counter.

6.1.1. Memory

AM memory is partitioned into segments which may be of unequal but fixed length. A program and its data will reside in memory segments. It is not necessary that code and data share the same segment, nor is it required that code and data be contiguous. The loader will determine from the origin directive where to load code and data values.

The AM heap is implemented as a set of operations which allocate and deallocate memory segments.

AM has a rich set of addressing modes which interact with a powerful move instruction which allows the programmer to move a value from "anywhere to anywhere."

61.2. Registers

AM registers form the high-speed storage into which operands are placed.

All atomic operations, such as add, divide and poffst, require operands to be in registers. Form operations are an exception. Their operands may be in either a register or a display register.

6.1.3. Display Registers

The form is the atomic data type that represents an image. Like any other atomic data type, it may be placed in any memory, register, stack or file cell. A form can not be "viewed" by the monitor unless it is in a display register.

Display registers may only contain form values. Each display register has its own window which is fixed in size but with a variable origin. The display window determines what part of the form is "viewed" by the monitor.

In general, display registers may be partitioned into multiple segments. However, the hardware on most machines will only support one segment of one or two registers. A segment of two display registers is equivalent to the idea of a "front" and "back" plane.

275

6.1.4. Monitor

The monitor represents a set of terminal attributes which are part of the "state of the machine." The attributes: vertical and horizontal number of pixels, vertical and horizontal screen dimensions, intensity capability and color planes are fixed for any terminal. The background color and display register selection attributes are programmable.

6.1.5. Stack

The AM stack is conventional in every respect except that it is impossible to access any value except the top. Thus, frames are implemented on the heap, not the stack.

AM has a typical set of push and pop instructions for operating on stacks.

6.1.6. Files

Input/output is implemented rather arbitrarily along the lines of system calls to an operating system and should not be considered part of AM itself.

Instructions are provided to open, close, read to and write from a file.

6.1.7. Queue

Primarily, the queue acts as a buffer for 'objects' being retrieved from the database during a select operation. It is implemented in the same way as the stack to prevent the accessing of any value except the one residing in the front position. This method ensures that the order of the values defining an object will be kept.

A set of write and read instructions is provided for operating on the queue.

6.1.8. Database

The database consists of two major parts: the data representing the information and a set of commands to perform the defined operations on it. These commands can only be applied to data that have explicitly been specified as a database and meet its structural requirements. In principle, the data need to be arranged as ordered pairs of lists. For database operations all resources of AM may be used, with exception of the display registers and the monitor.

Instructions are provided to open and close the database.

7.0 Atoms

An atom is a component of a data type. The assembler recognizes the following type of atoms:

    file address
    pidlist
    pidsetlist
    vallist
    valsetlist
    proplist
    propsetlist
    pvallist
    pvalsetlist
    objlist
    classlist
    dblist
    qaddress

As operands to instruction mnemonics, these atoms form the familiar set of literal and symbolic constants found in typical assembly language programs.

With certain exceptions, atoms may appear in the form of literal constants:

    100
    $d0fl
    'a'
    "this is a string atom"

They may also appear as symbols which take on the value of the atom in some other part of the source program. With few exceptions, anywhere a literal constant may be used, a symbolic constant of the appropriate type may also be used.

The assembler distinguishes between types of atoms using syntax and context. The syntax is described below.

7.1. Boolean

A boolean atom has only two values, true and false. These values are represented to the assembler by the decimal or hexadecimal constants for 1 and 0, respectively.

    0
    1
    $1
    $0

are legal boolean atoms.

7.2. Natural

This type represents as the name implies, the natural (unsigned) numbers. Legal values range from zero to positive

infinity. Natural numbers are represented to the assembler as
decimal or hexadecimal constants whose values are greater than
or equal to zero.

    0
    $2f5
    240

are legal natural atoms.

7.3. Integer

    Integers range from negative to positive infinity, and are
specified as hexadecimal or signed or unsigned decimal constants.

    -250
    0
    $ed67f
    +10

are legal integer atoms.

7.4. Character

    Character atoms may take values defined by the ASCII
character set. They are represented to the assembler as literal
character constants.

    'a'
    'r'

are legal character atoms.

7.5. String

    String atoms are composed of zero or more concatenated ACIII
characters. They are specified as literal strings.

    "this is a legal string atom"
    ""

are both legal string atoms.

7.6. Intensity

    An intensity atom ranges from 0 to 199 decimal. It is
represented as a unsigned decimal or hexadecimal constant pre-
ceded with the character "&." "@" represents the null intensity
which is used to construct the null color.

    &@
    &0
    &89
    &199

are legal intensity atoms.

7.7. Color

A color atom is a composite of a red, green and blue intensity. It is represented as an ordered triple of unsigned decimal or hexadecimal constants separated by commas ",", enclosed within parenthese "("")" and preceded with "&". The nullcolor provides the concept of background and transparency. It is represented as the "@" enclosed within parentheses and preceded with "&".

```
&(0,0,0)
&(70,0,190)
&@
```

are legal color atoms.

7.8. Point

Points are composed of integer pairs. The x and y coordinates correspond to the first and second integers respectively. Increasing integer values represents positions shifted right and up. A point is represented as an ordered pair of decimal or hexadecimal constants separated by a comma ","and enclosed within parentheses "("")".

```
(0,0)
(4,1047)
(-8,25)
(-50677,-293399)
```

are legal point atoms.

7.9. Rectangles

Rectangles are composed of a pair of points which represent the opposing corners. A rectangle is represented as an unordered pair of points separated by a colon ":" and enclosed within square brackets "[""]".

```
[(0,0):(0,0)]
[(0,0):(50,45)]
[(50,45):(0,0)]
[(-20,-20000):(30,59)]
```

are legal rectangle atoms.

7.10. Form

A form atom is a composite structure. It has a two dimensional size and a color map which is an array of colors with each color corresponding to a point in its area. The form atom has no literal constant representation. It is created using the operator, newfrm, and modified using other operators.

279

7.11. Font

A font atom is an array of forms. The font atom has no literal constant representation. It is constructed from the operator, newfnt, and modified using other operators.

7.12. Ptblt

A ptblt atom is a composite of three rectangles and a natural which represents a copy rule. The ptblt atom has no literal constant representation. It is constructed from the operator, newblt, and is modified using other operators.

7.13. Memory Address

Memory address atoms consist of two components: a segment address, and an element address. Memory addresses are represented as an ordered pair of unsigned decimal or hexadecimal constants, separated by a colon ":" and enclosed within parentheses "("")".

(0:100)

represents memory segment 0, element 100.

(2:$10)

represents segment 2, element 16.

Segment and element addresses start at 0. The number and size of available memory segments depends upon the current configuration of AM.

Labels are considered memory address atoms, as are names which appear to the left of the define storage and define constant directives.

7.14. Register Address

Register address atoms have a syntax identical to that of memory addresses except that a lower case "r" is prepended to the address.

r(0:3)

refers to register segment 0, register 3.

Segment and element addresses start, as with memory addresses, at 0. The number of register segments, and the number of registers within each segment, varies as determined by the current AM configuration.

7.15. Display Register Address

Display register address atoms have a syntax identical to that of register addresses except that the lower case "r" is replaced with a lower case "d".

d(0:1)

refers to display register segment 0, register 1.

Segment and element addresses start at 0. The number of display register segments, and the number of display registers within each segment, varies as determined by the current AM configuration.

7.16. Monitor Attribute

The monitor consists of eight attributes values which are:

x--represents number of horizontal pixels (natural)
y--represents number of vertical pixels (natural)
v--represents screen height in inches (natural)
h--represents screen width in inches (natural)
i--represents intensity capability (natural)
c--represents number of color planes (natural)
b--current background color (color)
d--selected display register to view
      (display register address)

A monitor attribute is represented by a dash "-" followed by one of the above characters for the indicated attribute.

-x
-y
-b

are all legal monitor attribute atoms.

7.17. Stack Address

A stack address has only one component: the segment address. Stack addresses are specified by prepending a lower case "s" to an unsigned decimal or hexadecimal constant enclosed within parentheses.

s(2)

refers to stack segment 2.

Stack addresses begin at 0. The number of stacks depends upon AM's configuration.

7.18. File Addresses

File address atoms may not appear in a program except within typed values. File address atoms are represented as unsigned integer or hexadecimal constants.

File addresses start at 0. The number of files which may be open at one time is determined by the current AM configuration. The first three file addresses (0,1,2) are normally opened automatically by AM when a program is loaded.

281

7.19. Pidlist

Pidlist atoms are composed of one or more concatenated ASCII characters and form single strings that must not be empty. They are surrounded by angle brackets.

```
<name>
<id>
<grade_1>
```

are all legal pidlist atoms.

7.20. Pidsetlist

This type represents a number of zero or more pidlists, separated by commas "," and enclosed within a set of angle brackets.

```
<name,age,grade>
<>
```

are both legal pidsetlist atoms.

7.21. Vallist

Vallists are represented like pidlists as strings of one or more concatenated ASCII characters. Type distinction is made in accordance with the context in which they appear. Arithmetic operations on vallist atoms are not possible since they are treated as characters.

```
<123>
<A>
```

are legal vallist atoms.

7.22. Valsetlist

Analogous to the pidsetlist, valsetlist atoms are composed of zero or more vallists, separated by commas "," and enclosed within a set of angle brackets. Since a valsetlist atom is actually used to define a certain domain of values, it most likely will be of the following form:

```
<1,2,3,4,17,123>
<A,B,C,D,E,F>
<Monterey,San_Diego>
<>
```

but

```
<John,Cindy,Monterey>
```

would also be a legal valsetlist atom.

7.23. Proplist

Proplists are composed of ordered pairs that consist of a pidlist and a valsetlist, additionally enclosed within angle brackets and separated by a comma ",".

```
< <name>,<John,Cindy,Mark> >
< <grade>,<A,A-,B+> >
```

are legal proplist atoms.

7.24. Propsetlist

Propsetlist atoms are represented by zero or more proplists, additionally enclosed within angle brackets and separated by commas ",". Since a proplist consists of the ordered pair pidlist and valsetlist, a propsetlist atom also contains a number of ordered pairs.

```
< < <name>,<John,Cindy,Mary> >,
  < <age>,<20,10,30,17,65>   > >
```

is a legal propsetlist atom.

7.25. Pvallist

This type is composed of the ordered pair pidlist and vallist separated by a comma "," and additionally enclosed within angle brackets.

```
< <name>,<John> >
< <name>,<Cindy> >
< <age>,<17> >
```

are legal pvallist atoms.

7.26. Pvalsetlist

A pvalsetlist atom consists of zero or more pvallists, separated by commas "," and additionally enclosed within angle brackets. It is arranged as a number of ordered pairs.

```
< < <name>,<John> >,< <age>,<25> >, < <city> <Monterey> > >
<<>>
```

are both legal pvalsetlist atoms.

7.27. Objlist

Objlists are composed of zero or more different pvallists and can be considered as particular pvalsetlists. An objlist consists of a number of ordered pairs that like a pvalsetlist, are enclosed within an additional set of angle brackets and separated by commas ",". It can be empty, although this would not be meaningful.

```
< < <name>,<John> > >
< < <name>,<Cindy> >,< <sex>,<female> >,< <age>,<20> > >
<<>>
```

are legal objlist atoms.

7.28. Classlist

This type is represented by zero or more objlists, additionally enclosed within angle brackets and separated by commas ",". It is mandatory that all objlists belonging to the same classlist are equally structured. That is, their pidlist atoms must be identical.

```
< < < <name>,<John > >,< <age>,<25> > >,
  < < <name>,<Cindy> >,< <age>,<19> > >,
  < < <name>,<Paul > >,< <age>,<20> > > >
```

is a legal classlist atom.

7.29. Dblist

The dblist is composed of zero or more classlists which are additionally enclosed within angle brackets and separated by commas ",". An objlist atom can only be contained in the dblist if it is part of a classlist that itself must be contained in the dblist. Since the structure is top-down, a pidlist not included in any classlist may be comprised in the dblist, but never the reverse.

The following shows a legal dblist atom:

```
< < < < <name>,<John> >,< <score>,<375> > >,
    < < <name>,<Mary> >,< <score>,<380> > > >,

  < < < <course>,<CS4600> >,< <room>,<13> >,< <hours>,<4.0> > >,
    < < <course>,<OR3333> >,< <room>,<42> >,< <hours>,<4.5> > > >,

  < < < <ID>,<ab> >,< <est>,<r19> > >,
    < < <ID>,<xy> >,< <est>,<o23> > >,
    < < <ID>,<vw> >,< <est>,<a95> > > > >
```

The database structure is simple and can easily be disclosed. The first list of this structure always corresponds to the first object class, while the first list of an object class is equivalent to its first object. Then the first list of an object represents its first property value which itself contains the property_id as first element and the corresponding value as its second.

7.30. Qaddress

The only component of a queue address is the segment address. Queue addresses are specified by prepending a lower case "q" to

an unsigned decimal or hexadecimal constant enclosed within parentheses.

    q(1)

refers to queue segment 1.

8. Typed Values

    Some of the atomic types may also appear as typed values in certain instructions and directives. A typed (immediate) value is represented as an ordered pair consisting of a key-word representing the type, and the atom itself, separated by a comma "," and enclosed within curly braces "{""}".

    {int.100}

represents the integer value 100.

    {addr.(1:100)}

represents memory address value (1:100).

    A list of the types which may be used as immediate values alongside the corresponding keywords appears below:

    bool--boolean
    nat--natural
    int--integer
    char--character
    string--character string
    intens--intensity
    color--color
    pnt--point
    rct--rectangle
    addr--memory address
    file--file address
    pidlist--property id list
    pidsetlist--property_idset list
    vallist--value list
    valsetlist--valueset list
    proplist--property list
    propsetlist--propertyset list
    pvallist--propertyvalue list
    pvalsetlist--propertyvalueset list
    objlist--object list
    classlist objectclass list
    dblist--database list

Immediate values are used, as in conventional assembly languages, for loading constants into cells, initializing storage, pushing parameters to subroutines on the stack, and so on.

    A special syntax may be applied when expressing typed values for the define storage and define directives. The type

285

keyword may be followed by a list of atoms of the appropriate
type, separated by commas.

    `{int,1,2,3,4,5,6,7,8}`

shows an example of this.

9. Expressions

An expression may be substituted anywhere an integer or
natural atom is called for. The expression must be a sequence
of integer/natural atoms (and symbolic constants equated to
integer/natural atoms) separated by operators and grouping
symbols which evaluates to an atom of the type called for
where the expression is used.

9.1. Expression Operators

Legal operators are (in order of increasing precedence):

```
|      - or
&      - and
+-     - addition and subtraction
*/%    - multiplication, division, and modulus
-      - unary minus
```

Expressions may be grouped using parentheses "("")".

10. Notation

Throughout the rest of this manual, the following notational
conventions will be used to describe the syntax of directives
and instructions.

```
A - atom
V - typed value
N - natural atom
I - integer atom
M - memory address atom
R - register address atom
D - display register address atom
C - either a display or a high speed register address atom
T - monitor attribute atom
S - stack address atom
< > - items enclosed within angle brackets are arguments
[] - items enclosed in square brackets are optional
<ea> - effective address
<ev> - effective value
Q - queue address atom
```

11. Data Format

AMASM emits object code and directives using AM I/O modules. The object module is, thus, directly readable by AM. A linker and loader may be written either in a high level language, or AM assembler.

The data and object module formats described below are a direct reflection of AM's tagged architecture. The following conventions will apply:

- All numbers shown are in hexadecimal.

- The letter "H" is a place holder signifying any 4-bit value.

- The letter "D" is a place holder signifying any 32-bit value.

- The letter "P" is a place holder signifying a 32-bit pointer.

- The general form of a typed value is

|tag| |val|

where "tag" is a 16-bit type field, and "val" is either an 8 to 32-bit value or a 32-bit pointer.

Note the following:

- Character string atoms and values have a 16-bit size field inserted after the type field which indicates the number of characters in the value field (including the terminating null). This size field is omitted in memory (since it is not needed) and replaced by a pointer to the string.

- Instruction values have a 32-bit pointer following the type field, which points to an array of values. The first value is the opcode followed by the operands. The number of operands is encoded in the opcode.

- Form values have a 32-bit pointer to a form header. The header contains the form's rectangle and a pointer to the cmap which is an array of colors. The length of the cmap is determined from the form's rectangle.

- Font values have a 32-bit pointer to a font header. The header contains the font' rectangle and a 128 member array of cmap pointers.

- All list atoms and values with the exception of the dblist type have a 16-bit size field that is inserted after the type field and indicates the number of characters contained in the value field. Similar to the string type, this size field is replaced in memory by a pointer to the corresponding list.

- Dblist atoms and values have a 32-bit size field inserted after the type field which indicates the number

287

END

FILMED

DTIC
MICROCOPY RESOLUTION TEST CHART
NATIONAL BUREAU OF STANDARDS-1963-A

of characters in the value field and represents the total
number of characters contained in the database. In
memory the size field is replaced by a 32-bit pointer to
the dblist.

A number of the formats listed below are not described else-
where in this manual since they are either not accessible to
the programmer, or are implied by context.

11.1. Atom Formats

boolean - |0001| |HH|

natural - |0002| |HHHH|

integer - |0003| |HHHH|

character - |0004| |HH|

character string - |0005| |P| |HH...00|

intensity - |0006| |HH|

color - |0007| |HH HH HH|

point - |0008| |P| |DD|

rectangle - |0009| |P| |DDDD|

form - |000A| |P| |DD DD| |P| |-cmap array-|

font - |000B| |P| |DD DD| |-128 P's-|

ptblt - |000C| |R| |DDDD DDDD DDDD HH|

memory address - |0030| |D|

register address - |0031| |D|

display register address - |0032| |D|

monitor attribute - |0033| |HH|

stack address - |0034| |D|

file address - |0035| |HHHH|

monadic operator - |0040| |HHHH|

dyadic operator - |0041| |HHHH|

triadic operator - |0042| |HHHH|

quadadic operator - |0043| |HHHH|

sexadic operator - |0044| |HHHH|

octadic operator - |0045| |HHHH|

relational operator - |0046| |HHHH|

boolean comparator - |0047| |HHHH|

pidlist - |000D| |P| |HH...00|

pidsetlist - |000E| |P| |HH...00|

```
vallist - |000F| |P| |HH...00|
valsetlist - |0010| |P| |HH...00|
proplist - |0011| |P| |HH...00|
propsetlist - |0012| |P| |HH...00|
pvallist - |0013| |P| |HH...00|
pvalsetlist - |0014| |P| |HH...00|
objlist - |0015| |P| |HH...00|
classlist - |0016| |P| |HH...00|
dblist - |0017| |P| |D...00|
qaddress - |0036| |D|
```

11.2. Value Formats

```
boolean - |0201| |HH|
natural - |0202| |HHHH|
integer - |0203| |HHHH|
character - |0204| |HH|
character string - |0205| |P| |HH...00|
intensity - |0206| |HH|
color - |0207| |HH HH HH|
point - |0208| |P| |DD|
rectangle - |0209| |P| |DDDD|
form - |020A| |P| |DD DD| |P| |-cmap array-|
font - |020B| |P| |DD DD| |-128P's-|
ptblt - |020C| |P| |DDDD DDDD DDDD HH|

qaddress - ⌐0236⌐  ⌐D⌐
```

11.3. Object Module Format

The structure of an object module is very simple. The only object always found is a leading org directive. Next, if any symbols were declared global or external in the source module, a pseudo instruction will be emitted for each such symbol. The rest of the file contains executable and pseudo instructions emitted as they occur in the source.

12. Assembler Directives

AMASM recognizes the following directives:

```
equ     - equate
org     - absolute origin
rorg    - relative origin
extern  - external symbol
globl   - global symbol
trace   - trace execution
ds      - define stroage
dc      - define constant
```

Directives do not produce code which will be executed by AM, but they may cause linker/loader instructions to be emitted. The meaning and syntax of each directive is described in the following pages.

Syntax:

    <name> equ <equivalence>

    where:
    <name> is any legal identifier
    <equivalence> is any atom or typed value

Description:

    The symbol <name> is assigned the value of <equivalence>.
Elsewhere in the source module, the symbol may be used in place
of a literal value of the same type as <equivalence> using the
following syntax:

    - If the symbol represents a memory address atom, the symbol
      may be used directly.

    - If the symbol represents a typed (immediate) value, it
      must be enclosed in curly braces "{""}".

    - If the symbol represents an integer or natural atom, it
      must be preceded by a pound sign "#".

Example:

```
    propseg     equ   (0:0)
    dataseg     equ   (1:100)
    offset      equ   10
    datafile    equ    file,3

                org   progseg
                move  {addr,data},r(0:0)
                move  {int,100},r(0:0)@#offset

                push  {string,"test.dat"}s(0)
                push  {datafile},s(0)
                push  {int,0},s(0)
                push  {int,0},s(0)
                open  s(0)
                stop

                org   dataseg
    data        ds    100
```

"progseg" and "dataseg" are equated to memory address atoms.

"offset" is equated to the integer atom 10.

"datafile" is equated to the file address value {file,3}.

291

Format:

   equ does not cause an emission.

Syntax:

    org [M]

Description:

    The location counter is reset to M, if specified; other-
wise it remains unchanged. All memory addresses and labels
specified after an org directive up to the next org or rorg
directive not explicitly expressed as displacements are
treated as absolute addresses. Code generated after an org
directive up to the next org or rorg directive is not
relocatable.

Example:

                org

                move   (0:0),r(0:0)

                org   (1:0)
    data   ds   {int,100},{nat,0}

Format:

    |0250| |1801| |0230| |D|

Syntax:

    rorg [M[

Description:

    The location counter is reset to M, if specified; other-
wise it remains unchanged. All memory addresses and labels
specified after a rorg directive up to the next org or rorg
directive are computer as displacements. Code generated after
a rorg directive up to the next org or rorg directive is
relocatable (program counter independent).

Example:

                rorg

                move {int,100},data
                jsr   stuff
                stop

    data   ds   10

    In the above example, the move would be emitted using
destination program counter relative addressing.

Format:

    |0250| |1801| |0230| |D|

Syntax:

    extern <name>...

    where:
    <name> is any legal identifier

Description:

    The list of symbols is made visible to the current module
and is assumed to be defined elsewhere. An error is flagged
if a symbol in the list is not referenced somewhere within
the current module. It is also an error for any symbol in
the list to be defined within the current module.

Example:

```
extern expon

push   {int,100},s(0)
jsr    expon,s(0)
```

Format:

    For each symbol decalred external, an extern pseudo op is
emitted, followed by a string containing the symbol.

0250	1802	0205	P	HH...00

Syntax:

        globl <name>...

        where:
        <name> is any legal identifier

Description:

        The list of symbols is made visible to external modules.
Each name in the list must be defined as a memory address
somewhere within the current module.

Example:

                globl   test,data

        test:

                move   (0:0),r(0:0)
                stop
        data   ds   10

        "test" and "data" are made visible to other modules.

Format:

        For each symbol declared global, a globl pseudo op is
emitted, followed by a string containing the symbol, followed
by a memory address representing the value of the symbol.

        0250   1803   0005   P   HH...00   0230   D

Syntax:

    trace <flag>,<toggle>

    where:
    <flag> is "-t" for normal trace and "-x" is for extended
      trace
    <toggle> is "+" for on and "-" for off

Description:

    A trace of the programs execution is available in two
modes, normal and extended. The normal mode traces the main
function calls and the major paths through them. The extend
mode includes the normal trace plus memory allocation calls and
creation of temporary values. The trace directive may be
selected in the command line when AM is invoked, or embedded
in the source code to enable trace over selected portions of
the program.

Example:

```
progseg           equ    (0:0)
          org    progseg
          move   {addr,data},r(0:0)
          trace -t,+
          move   {int,100},r(0:0)@
          trace -t,-
          push   {int,0},s(0)
          stop
data      ds     100
```

Format:

    0250   3800   0204   HH   0203   HHHH

Syntax:

    [<name>] ds N[V...]
    [<name>] ds [N] V...

    where:
    <name> is an optional identifier

    ds permits a list of atoms to follow the type keyword of
      each value.

Description:

    ds allocates storage for values starting at the current
value of the location counter.

    - If N is specified and N is greater than or equal to the
      number of values in the list, space for N values is
      allocated and the location counter is incremented by N.

    - If N is specified and N is less than the number of values
      in the list, N is ignored.

    - If N is not specified, the amount of storage allocated
      is equal to the number of values in the list. The loca-
      tion counter is incremented by this number.

    - If a value list is specified, the allocated cells will
      be initialized to those values, beginning with the first.

    - Cells allocated but not initialized are considered to
      hold undefined values. It is an error to attempt to
      read an undefined value.

Example:

    data 1   ds   10
    data2   ds   10{int,100},{nat,0,20,40}
    data3   ds   {char,'a','b'}
                ds   {string,"this is a string value"}

    The first ds allocates 10 values and leaves them undefined.
    "data1" may be used to index into those values.

    The second also allocates 10 values, but initializes the
    first to the integer 100, and the next 3 to the naturals
    0, 20, and 40. The last 6 values are left undefined.

    The third ds shown allocates 2 character values.

The fourth allocates a single string value. No identifier was specified.

Format:

A typed value is emitted for each value in the list. In addition, ds will emit an org pseudo op (see org) whenever the number of values in the value list is less than N.

Syntax:

    [<name>] dc V...

    where:
    <name> is an optional identifier

    dc permits a list of atoms to follow the type keyword of
    each value.

Description:

    dc allocates and initializes storage from a list of values
starting at the current value of the location counter.

Example:

    data3   dc   {char,'a','b'}
                 dc   {string,"this is a string value"}

    The first ds shown allocates 2 character values.

    The second allocates a single string value. No identi-
    fier was specified.

Format:

    A typed value is emitted for each value in the list.

13. Addressing Modes

AM supports 11 addressing modes:

d   - display register direct
r   - register direct
ri   - register indirect
rid   - register indirect with displacement
ridn - n-level register indirect with displacement
m   - memory absolute
mi   - memory indirect
pcr   - program counter relative
i   - immediate value
a   - immediate atom
s   - stack direct
q   - queue direct

Like other more familiar processors, not all AM instructions
can use all of the addressing modes.

In addition, AMASM supports address expressions, which
provides a rudimentary indexing capability.

13.1. Display Register Direct

The form operand is in the display register.

Syntax: D

Format:

    `0232` `D`

13.2. Register Direct

The operand is in a register.

Syntax: R

Format:

    `0231` `D`

13.3. Register Indirect

The address of the operand is in a register.

Syntax: R@

    R   - holds the operand address

Format:

    `0231` `D`

301

13.4. Register Indirect with Displacement

The address of the operand is the sum of the address in a register and an integer displacement.

Syntax: R@I

    R   - holds a base address
    I   - an integer displacement

Format:

| 0231 | D | 0203 | HHHH |

13.5. N-level Register Indirect with Displacement

The address of the operand is the sum of the address obtained from the nth link in a chain of dynamic links and an integer displacement.

Syntax: RN@I

    R   - holds the current frame pointer
    N   - a non-negative frame reference
    I   - an integer frame displacement

    (RN@I) is equivelent to R@I)

Format:

| 0231 | D | 0202 | HHHH | 0203 | HHHH |

13.6. Memory Absolute

Syntax: M

    M   - the operand address

Format:

| 0230 | D |

13.7. Memory Indirect

The address of the operand is in a memory cell.

Syntax: M@

    M   - a pointer to the operand address

Format:

| 0230 | D |

13.8. Program Counter Relative

The address of the operand is the sum of the program counter and an integer displacement.

Syntax: M

    M   - the operand address

The specified address must be in the same module as the instruction. The assembler automatically computes the displacement. Program counter relative is specified for a block by placing a rorg directive at the top of the block.

Format:

    | 0203 | | D |

13.9. Immediate Value

The operand is an immediate value.

Syntax: V

    V   - any typed value

Format:

    | tag | | valu |

13.11. Stack Direct

The operand is a stack.

Syntax: S

Format:

    | 0234 | | D |

13.12. Queue Direct

The operand is a queue.

Syntax: Q

Format:

    | 0236 | | D |

14. Instruction Set

The AM instruction set is simple but powerful. The rigid data types make it meaningless to specify operations like shift and mask, thus removing some of the programmer's freedom to

muck with data in arbitrary ways. The tagged architecture will detect errors like jumping to data, or accessing instructions as data, as well as the more common bounds checking performed by runtime libraries.

141. Machine Errors

The following errors are detected by AM during loading and execution:

- attempt to execute a non-instruction
- attempt to execute an illegal instruction
- memory segment not defined
- memory segment overflow
- memory segment underflow
- register segment not defined
- register segment underflow
- register segment underflow
- display register segment not defined
- stack segment not defined
- undefined monitor attribute
- <file> contains unresolved references
- attempt to convert negative int to nat
- no predecessor to zeronat
- no predecessor to minintens
- no successor to maxintens
- addition illegal with nullintens
- subtraction illegal with nullintens
- gtintens illegal with nullintens
- ltintens illegal with nullintens
- geintens illegal with nullintens
- leintens illegal with nullintens
- illegal color definition
- form is not correct size for font
- icon is undefined
- unknown operator to applymop
- unknown operator to applydop
- unknown operator to applytop
- unknown operator to applyqop
- unknown operator to applysop
- unknown operator to applyoop
- unknown operator to applyrop
- unknown operator to applybop
- type error - GT
- type error - GE
- type error - LT

All machine errors are fatal.

14.2. Assembler Errors

AMASM will detect and report the following errors:
- symbol not an address
- symbol defined locally
- <symbol> does not match declared type
- relative memory indirect not permitted
- symbol not a value
- symbol not an integer
- intensity value exceeds range
- symbols declared but not referenced
- displacement from external addresses not permitted
- relative addressing not permitted between segments
- out of symbol space
- symbol declared external
- symbol already defined
- symbol not of same type
- impossible value for given type
- syntax error

Assembler errors are not fatal, but will prevent the creation of the object module and, usually, the cross-reference file.

14.3. AM Operations

AM supports a useful set of monadic, dyadic, triadic, quadadic, sexadic, octadic, relational and test operators. These operators are to be used with the monad, dyad, triad, quad, sexad, octad, if and test instructions. The mnemonics/symbols for each operator along with the data types to which each may be applied are described below.

14.3.1. Monadic Operators (MOP's)

not - boolean negation

   not accepts a boolean argument and returns its negation

abs - absolute value

   abs accepts an integer argument and returns is absolute value

ntoi - natural to integer

   ntoi accepts a natural argument and converts it to an integer

iton - integer to natural

   iton accepts an integer argument and converts it to a natural

307

len - string length

> len accepts a string argument and returns its length as
> a natural number.

make - make a string

> This operator accepts a character argument and returns a
> string of length 1.

head - the head of a string

> This operator accepts a string argument and returns the
> character at its head. It is an error to take the head
> of an empty string.

tail - the rest of a string

> tail accepts a string argument and returns a string con-
> taining all but the first character. The tail of an
> empty string is the empty string.

remp,gcmp,bcmp - color components

> remp, gcmp and bcmp accept a color argument and return
> the respective red, green, or blue component of the
> color.

xcord,ycord - point coordinate

> xcord and ycord accept a point argument and return the
> respective coordinate integer.

origin,corner - rectangle corner points

> These operators accept a rectangle argument and return a
> corner point. Origin returns the lower left and corner
> the upper right.

xdim,ydim - rectangle dimensions

> xdim and ydim accept a rectangle argument and return the
> respective dimension integer.

newfrm - new form

> newfrm accepts a rectangle argument and returns a new blank
> form whose rectangle is the same as the input rectangle.

farea - form area

> farea accepts a form argument and returns its rectangle.

gblts,gbltd,gbltc - get ptblt rectangles

> These operators accept a ptblt argument and return the
> specified rectangle. gblts returns the source, gbltd
> returns the destination, and gbltc returns the clipping
> rectangle.

gbltr - get ptblt rule

   gbltr accepts a ptblt argument and returns the natural
   that represents the copy rule.

newfnt - new font

   newfnt accepts a rectangle argument and returns an empty
   font whose icon rectangles are the same as the input
   rectangle.

rctfnt - rectangle of font

   rctfnt accepts a font argument and returns its rectangle.

lenfnt - length of font

   lenfnt accepts a font argument and returns the number of
   icons in it as a natural.

makenew - make a list

   This operator accepts a list argument and returns a new
   list.

first - the first list

   first accepts a list argument and returns the first list
   contained in it. It is an error to take the first of an
   empty list.

rest - the rest of a list

   rest accepts a list argument and returns a list containing
   all but the first list. It is an error to apply this
   operator to the empty list.

sofirst - set of first lists

   This operator accepts a list and returns the set of all
   first lists contained in it. Applying sofirst to a list
   which does not contain at least two sublists results in
   an error.

14.3.2. Dyadic Operators (DOP's)

and,or

   and and or accept two boolean arguments and return a boolean
   result.

add,sub,mul,div,mod - computational operators

   These operators accept integer, natural or intensity argu-
   ments (both of the same type) and return a result of that
   type. Divide by zero returns an error. div discards any
   remainder. mod returns the remainder. mul, div and mod
   do not apply to intensity arguments.

309

cat - string concatenation

cat accepts two string arguments and returns the concatenation of the first onto the second.

loc - point location

loc accepts two integer arguments and returns the defined point.

Usage - loc(x,y) where x is the x coordinate integer and y is the y coordinate integer.

area - rectangle definition

area accepts two unordered point arguments and returns the defined rectangle.

inrct - point in rectangle

inrct accepts a point and a rectangle argument, checks if the point is inside the area of the rectangle, and returns the boolean result.

Usage - inrct(p,r) where p is a point and r is a rectangle.

intrct - rectangle intersection

intrct accepts two rectangle arguments and returns the intersection rectangle.

putrct - put rectangle at

putrct accepts a point and a rectangle argument and returns the rectangle with the same area as the input and its origin at the point argument.

Usage - putrct(p,r) where p is a point and r is a rectangle.

mapsp,mapps - conversion operators

These operators convert points between point coordinates and font spot coordinates. They accept a point and a font argument and return a point. mapsp takes a spot coordinate and based on the font size returns its origin point, e.g., the origin point of spot (2,3) for a 10 by 10 font is point (20,30). mapps takes a point and returns the font spot that it falls inside, e.g., the point (21,31) for a 10 by 10 font is in spot (2,3).

Usage:

- mapsp(f,p) where f is a font and p is a point,

- mapps(f,p) where f is a font and p is a point.

310

gcolor - get color

>gcolor accepts a point and a form argument and returns the form's color at that point.

>Usage - gcolor (p,f) where p is a point and f is a font.

fill - fill the form

>fill accepts a color and a form and returns the from with all its points set to the color argument.

>Usage - fill(c,f) where c is a color and f is a font.

sblts,sbltd,sbltc - set ptblt rectangles

>These operators accept a rectangle and a ptblt argument and return the ptblt with the specified rectangle set to the rectangle argument.

>sblts sets the source, sbltd sets the detaintion, and sbltc sets the clipping rectangle.

>Usage - sblt_(r,b) where r is a rectangle and b is ptblt.

sbltr - set ptblt rule

>sbltr accepts a natural and a ptblt argument and returns the ptblt with copy rule set to the natural arqument.

>Usage - sbltr(n,b) where n is a natural and b is ptblt.

infnt - is icon in font

>infnt accepts a natural and a font argument and returns a boolean result based on whether the icon indexed by the nautral argument is defined.

>Usage - infnt(n,f) where n is a natural and f is a font.

dfnt - delete icon

>dfnt accepts a natural and a font argument and returns the font with the indexed icon deleted.

>Usage - dfnt(n,f) where n is a natural and f is a font.

gfnt - get icon

>gfnt accepts a natural and a font argument and returns the form of the icon indexed.

>Usage - gfnt(n,f) where n is a natural and f is a font.

un - union of lists

>un accepts two lists as arguments and returns the union of both.

int - intersection of lists

> int accepts two list arguments and returns the intersection of both.

cat - list concatenation

This operator accepts two list arguments and returns the concatenation of the first list onto the second.

get - get a list

> get accepts two list arguments and returns the list from the first argument that corresponds with the second. If any of the two arguments is the empty list the operation results in an error.

de - delete a list

This operator accepts two list arguments and returns a list that is equal to the second argument but reduced by the list indicated by the first argument. It is an error to apply de to an empty list or to specify a first argument that is not contained in the second.

retobj - retrieve an object

> retobj accepts two list arguments and returns the list that corresponds to the second argument. If the second argument is the empty list the result will also be the empty list.

14.3.3. Triadic Operators (TOP's)

dcolor - define color

> dcolor accepts three intensity arguments and returns the defined color.

> Usage - dcolor(r,g,b) where r is the red intensity, g is the green intensity, and b is the blue intensity.

poffst

> poffst accepts a point and two integer arguments and returns the point that is offset from the point argument by the integer arguments.

> Usage - poffst(x,y,p) where x and y are the offset integers and p is the reference point.

sftrct - shift rectangle

> sftrct accepts a rectangle and two integer arguments and returns the rectangle formed by offsetting its origin by the integer arguments.

Usage - sftrct(x,y,r) where x and y are the offset integers and r is the reference rectangle.

scolor - set color

scolor accepts a color, a point and a form argument and returns the form with its point argument set to the color argument.

Usage - scolor(p,c,f) where p is the point, c is the color, and f is the font.

invfrm - inverse form

invfrm accepts a form and two color arguments and returns the form with its fore and background colors inversed by the color arguments.

Usage - invfrm(fg,bg,frm) where fg is the new foreground color, bg is the new background color, and frm is the form to be inversed.

sfnt - set font

sfnt accepts a natural, a form, and a font and returns the font with the new icon inserted that is defined by the form and natural arguments.

Usage - sfnt(frm,n,fnt) where frm is the icon form, n is the index, and fnt is the font.

mod - modify list

mod accepts a dblist, an objlist, and a pvallist and returns the dblist with the new pvallist inserted into the appropriate position of the objlist identified by the corresponding 'pid.' It is an error to apply a pvallist to an object for which it is not defined.

14.3.4. Quadadic Operators (QOP's)

foffst - font offset

foffst accepts two integer arguments as an offset, a point argument and a font argument. It returns the spot origin point based on the spot coordinate offset from the point argument, e.g., a font size of 10 by 10 which is offset 2,3 from point (5,5) returns the spot origin point at (25,35).

Usage - foffst(x,y,fnt,p) where x and y are the offset integers, fnt is the basis font, and, p is the reference point.

cpfrm - form copyblt

cpfrm merges a source and a mask form with a destination
form using the parameters in ptblt. It accepts a ptblt
and three form arguments and returns the resultant form.

Usage - cpfrm(pb,s,m,d) where pb is the governing ptblt,
s is the source form, m is the mask form, and d is the
destination form.

14.3.5. Sexadic Operators (SOP's)

drawln - draw line

drawln draws a line from point y to point z on the destina-
tion form, using the specified brush and mask forms. It
accepts two point arguments, three form arguments and a
ptblt argument and returns a form.

Usage - drawln(x,y,pb,b,m,d) where y is the start point,
z is the end point, pb is the ptblt, b is the brush form,
m is the mask form, and d is the destination form.

cpfnt - copy font

cpfnt copies a font icon to a designated point on the des-
tination form. It accepts a natural and a font argument
which defines the source form, a point argument for the
target location, two form arguments and a ptblt argument
and returns the resultant form.

Usage - cpfnt(p,pb,n,fnt,m,d) where p is the target location,
pb is the ptblt, n is the font index; fnt is the font, m
is the mask form, and d is the destination form.

14.3.6. Octadic Operators (OOP's)

invfnt - inverse font

invfnt performs the same operation as cpfnt except that
the font icon is combined with inverse coloring. It
accepts the same arguments plus two color arguments and
returns the resultant form.

Usage - invfnt(fg,bg,p,pb,n,fnt,m,d) where fg is the new
foreground color, bg is the new background color, p is
the target location, pb is the ptblt, n is the font index,
fnt is the font, m is the mask form, and d is the destina-
tion form.

14.3.7. Relational Operators (ROP's)

The relational operators are:

==   - equality
>   - greater than

314

```
>=  - greater than or equal to
<   - less than
<=  - less than or equal to
!=  - not equal to
```

They may be applied to int, nat, char, string, intens, pnt, and lst.

If == or != are applied to arguments of different types, == returns false, != returns true. This applies also to types not listed above. >,>=,< and <= return an error if their arguments are not of the same type.

Relational operators return a boolean result.

14.3.8. Test Operators (BOP's)

These operators permit the programmer to test a cell for type before attempting to access it. These are necessary because AM considers it a fatal error to read from an undefined cell or apply an operator of one type on data of another. The test operators are the same as the type mnemonics, plus a mnemonic for testing undefined values:

```
bool
nat
int
char
string
intens
color
pnt
rct
form
font
ptblt
instr
addr
file
undef
pid
val
pval
obj
db
lst
```

Test operators accept a typed value and return true if the value is of the specified type, false otherwise. undef returns true if a value is undefined, false otherwise.

Syntax:

    offset I,R

    R must contain a memory address value

Operation:

    R + I --> R

Description:

    The sum of I and the address in R is stored in R.

Example:

                    offset 20,r(0:0)

Addressing Modes:

    I: a

    R: r

Format:

    | 0250 | P | 3810 | operands |

Syntax:

    link R,N

Operation:

    R@ --> address@
    address --> R

Description:

    A segment of N cells is allocated from the heap. The
value stored in R is save at the base address of the segment.
The segment base address is returned in R.

    This instruction is designed to create dynamic links for
local environments.

Example:

    proc: link   r(0:5),1
                   move   r(0:5)2@4,r(0:0)
                   add   {int,100},r(0:0)
                   move   r(0:0),r(0:5)2@4
                   unlink r(0:5)
                   rts

    Above is an example of uplevel addressing.

Addressing Modes:

    R: r

    N: a

Format:

    |0250| |P| |3811| |operands|

Syntax:

    unlink R

Operation:

    R@ --> R

Description:

    The value in the base address of the segment pointed to
by R is returned in R. The segment is freed.

Example:

    proc: link   r(0:5),1
                  move   r(0:5)2@4,r(0:0)
                  add   {int,100},r(0:0)
                  move   r(0:0),r(0:5)2@4
                  unlink r(0:5)
                  rts

Addressing Modes:

    R: r

Format:

    | 0250 | | P | | 2812 | | operand |

318

Syntax:

    gdwin D,R

Operation:

    D --> R

Description:

    The value of the display window origin point at D is
    stored in R.

Example:

                    gdwin d(0:0),r(0:0)

Addressing Modes:

    R: r

Format:

    |0250| |P| |3813| |operands|

Syntax:

    sdwin R,D

    R must contain a point value

Operation:

    R --> D

Description:

    The display window origin point at D is set to the point
value in R.

Example:

                    sdwin r(0:0),d(0:0)

Addressing Modes:

    R: r

Format:

    | 0250 | | P | | 3814 | | operands |

Syntax:

    gmtr T,R

Operation:

    T --> R

Description:

    The T value is stored in R.

Example:

                gmtr   -b,r(0:0)

Addressing Modes:

    R: r

Format:

    |0250| |P| { |2815| ... |281C| } |operand|

Syntax:

    smtr R,T

    R must contain a value appropriate for the selected
attribute.

Operation:

    R --> T

Description:

    The T value is set to the value in R

Example:

                    smtr   r(0:0),-d

Addressing Modes:

    R: r

Format:

    | 0250 | | P | { | 281D | ... | 2824 | } | operand |

Syntax:

    <mop> C

    where:
    <mop> is a monadic operator

Operation:

    <mop> C --> C

Description:

    The operator corresponding to mop is applied to C and
the result stored in C.

Example:

                    not   r(0:0)

Addressing Modes:

    C: r,d

Format:

    | 0250 | | P | | 3830 | | operand |

Syntax:

    <mop> Cx,Cy

    where:
    <mop> is a monadic operator

Operation:

    <mop> Cx --> Cy

Description:

    The operator corresponding to mop is applied to Cx and
the result stored in Cy.

Example:

                not   r(0:0),r(1:0)
                farea   d(0:0),r(0:0)

Addressing Modes:

    Cx: r,d

    Cy: r,d

Format:

    |0250| |P| |4831| |operands|

Syntax:

    <mop> V,C

    where:
    <mop> is a monadic operator

Operation:

    <mop> V --> C

Description:

    The operator corresponding to <mop> is applied to the
immediate value V and the result stored in C.

Example:

                not   (addr,flag),r(1:0)
                newfrm   (addr,rctsize),d(0:0)

Addressing Modes:

    V: i

    C: r,d

Format:

    | 0250 | P | 4832 | operands |

325

Syntax:

    <dop> Cx,Cy

    where:
    <dop> is a dyadic operator

Operation:

    Cy <dop> Cs --> Cy

Description:

    The operation corresponding to <dop> is applied to the
operands and the result stored in Cy.

Example:

                    and   r(0:0),r(0:1)
                    fill   r(0:0),d(0:0)

Addressing Modes:

    Cx: r,d

    Cy: r,d

Format:

    `0250` `P` `4833` `operands`

326

Syntax:

    <dop> V,C

    where:
    <dop> is a dyadic operator

Operation:

    C <dop> V --- C

Description:

    The operation corresponding to dop is applied to the
operands and the result stored in C.

Example:

```
            sub    (int,100),r(0:1)
            fill   (color,&(10,10,10)),d(0:0)
```

Addressing Modes:

    V: i

    C: r,d

Format:

0250	P	4834	operands

Syntax:

    <dop> Cx,Cy,Cz

    where:
    <dop> is a dyadic operator

Operation:

    Cy <dop> Cx --> Cz

Description:

    The operation corresponding to <dop> is applied to Cx and
Cy and the result stored in Cz.

Example:

                    add   r(0:0),r(0:1),r(0:3)
                    gcolor r(0:0),d(0:0),r(0:1)

    <dop> Cx,Cy,Cy is equivalent to <dop> Cx,Cy

Addressing Modes:

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    |0250| |P| |4835| |operands|

328

Syntax:

    <dop> V,Cx,Cy

    where:
    <dop> is a dyadic operator

Operation:

    Cx <dop> V --> Cy

Description:

    The operation corresponding to <dop> is applied to V and
Cx and the result stored in Cy.

Example:

                add   {int,100},r(0:0),r(0:1)
                gcolor {pnt,(0,0)},d(0:0),r(0:0)

    <dop> V,Cx,Cx is equivalent to <dop> V,Cx

Addressing Modes:

    V: i

    Cx: r,d

    Cy: r,d

Format:

    |0250| |P| |4836| |operands|

329

Syntax:

    <top> Cx,Cy,Cz

    where:
    <top> is a triadic operator

Operation:

    <top> Cx,Cy,Cz --> Cz

Description:

    The operation corresponding to <top> is applied to the
operands and the result stored in Cz.

Example:

                sfnt   .r(0:0),r(0:1),r(0:2)

Addressing Modes:

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    | 0250 | | P | | 4837 | | operands |

Syntax:

    <top> Cw,Cx,Cy,Cz

    where:
    <top> is a triadic operator

Operation:

    <top> Cw,Cx,Cy --> Cz

Description:

    The operation corresponding to <top> is applied to the operands and the result stored in Cz.

Example:

            scolor r(0:0),r(0:1),d(0:2),r(0:3)

Addressing Modes:

    Cw: r,d

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    | 0250 | | P | | 4838 | | operands |

Syntax:

    <qop> Cw,Cx,Cy,Cz

    where:
    <qop> is a quadadic operator

Operation:

    <qop> Cw,Cx,Cy,Cz --> Cz

Description:

    The operation corresponding to <qop> is applied to the
operands and the result stored in Cz.

Example:

                cpfrm r(0:0),d(0:0),r(0:1),d(0:1)

Addressing Modes:

    Cw: r,d

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    |0250| |P| |4839| |operands|

Syntax:

    <qop> Cv,Cw,Cx,Cy,Cz

    where:
    <qop> is a quadadic operator

Operation:

    <qop> Cv,Cw,Cx,Cy --> Cz

Description:

    The operation corresponding to <qop> is applied to the
operands and the result stored in Cz.

Example:

                cpfrm r(0:0),r(0:1),r(0:2),r(0:3),d(0:0)

Addressing Modes:

    Cv: r,d

    Cw: r,d

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    | 0250 | | P | | 483A | | operands |

Syntax:

     <sop> Cu,Cv,Cw,Cx,Cy,Cz

     where:
     <sop> is a sexadic operator

Operation:

     <sop> Cu,Cv,Cw,Cx,Cy,Cz --> Cz

Description:

     The operation corresponding to <sop> is applied to the
operands and the result stored in Cz.

Example:

                    drawln   r(0:0),r(0:1),r(0:2),r(0:3),r(0:4),d(0:0)

Addressing Modes:

     Cu: r,d

     Cv: r,d

     Cw: r,d

     Cx: r,d

     Cy: r,d

     Cz: r,d

Format:

     | 0250 | P | 483B | operands |

334

Syntax:

     <sop> Ct,Cu,Cv,Cw,Cx,Cy,Cz

     where:
     <sop> is a sexadic operator

Operation:

     <sop> Ct,Cu,Cv,Cw,Cx,Cy --> Cz

Description:

     The operation corresponding to <sop> is applied to the
operands and the result stored in Cz.

Example:

                    cpfnt   r(0:0),r(0:1),r(0:2),r(0:3),r(0:4),
                            d(0:0),d(0:1)

Addressing Modes:

     Ct: r,d

     Cu: r,d

     Cv: r,d

     Cw: r,d

     Cx: r,d

     Cy: r,d

     Cz: r,d

Format:

     | 0250 | | P | | 483C | | operands |

335

Syntax:

    <oop> CsçCt,Cu,Cv,Cw,Cx,Cy,Cz

    where:
    <oop> is a octadic operator

Operation:

    <oop> Cs,Ct,Cu,Cv,Cw,Cx,Cy,Cz --> Cz

Description:

    The operation corresponding to <oop> is applied to the
operands and the result stored in Cz.

Example:

        invfnt r(0:0),r(0:1),r(0:2),r(0:3),r(0:4),r(0:5),
               r(0:6),d(0:1)

Addressing Modes:

    Cs: r,d

    Ct: r,d

    Cu: r,d

    Cv: r,d

    Cw: r,d

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    |0250| |P| |483D| |operands|

336

Syntax:

    <oop> Cr,Cs,Ct,Cu,Cv,Cw,Cx,Cy,Cz

    where:
    <oop> is a octadic operator

Operation:

    <oop> Cr,Cs,Ct,Cu,Cv,Cw,Cx,Cy --> Cz

Description:

    The operation corresponding to <oop> is applied to the
operands and the result stored in Cz.

Example:

        invfnt r(0:0),r(0:1),r(0:2),r(0:3),r(0:4),r(0:5),
                r(0:6),d(0:0),d(0:1)

Addressing Modes:

    Cr: r,d

    Cs: r,d

    Ct: r,d

    Cu: r,d

    Cv: r,d

    Cw: r,d

    Cx: r,d

    Cy: r,d

    Cz: r,d

Format:

    |0250| |P| |483E| |operands|

Syntax:

    move <ea1>,<ea2>

    where:
    <ea> must be one of the addressing modes listed below

Operation:

    source --> destination

Description:

    The value found at the source address is copied into
the destination address.

Example:

                move r(0:0),d(0:0)
                move d(0:1),r(0:4)
                move r(0:0),data
                move {addr,data},r(0:20)
                move {int,100},r(0:20)@
                move r(0:20)@10,r(0:10)

    data: ds 100

Addressing Modes:

    <ea1>: d,r,ri,rid,ridn,m,pcr,i

    <ea2>: d,r,ri,rid,ridn,m,pcr

Format:
    | 0250 | | P | { | H850 | ... | H884 | }| operands |

Syntax:

    push <ea>,S

    where:
    <ea> is one of the addressing modes listed below

Operation:

    source --> S

Description:

    The source value is pushed onto stack S. The programmer
has no access to the stack pointer.

Example:

                push {int,100},s(0)   .
                push r(0:10),s(1)
                push d(0:0),s(1)

Addressing Modes:

    <ea>: d,m,pcr,r,ri,rid,ridn,i

    S: s

Format:

    | 0250 | | P |{| H880 | ... | H887 |}| operands |

Syntax:

    pop S,<ea>

    where:
    <ea> is one of the addressing modes listed below

Operation:

    S --> destination

Description:

    The source value is popped off stack S and stored at <ea>.
The programmer has no access to the stack pointer.

    It is an error to attempt to pop a value from an empty
stack.

Example:

```
            pop s(0),r(0:1)
            pop s(0),data
            pop s(1),d(0:0)
```

    data: ds 1

Addressing Modes:

    S: s

    <ea>: d,m,pcr,r,ri,rid,ridn

Format:

    $\boxed{0250}$ $\boxed{P}$ { $\boxed{H889}$ ... $\boxed{H88f}$ } $\boxed{\text{operands}}$

Syntax:

    popx S

Operation:

    S -->

Description:

    The top value of stack S is removed.

    It is an error to attempt to remove the top of an empty
stack.

Example:

                popx s(0)

Addressing Modes:

    S, s

Format:

    |0250| |P| |2888| |operands|

Syntax:

    nop

Operation:

    -

Description:

    Does nothing.

Addressing Modes:

    -

Format:

    | 0250 | | P | | 18A0 |

STOP   Halt Execution   STOP

Syntax:

    stop

Operation:

    -

Description:

    Execution is terminated.

Addressing Modes:

    -

Format:

    | 0250 | | P | | 18A1 |

Syntax:

    jmp <ea>

    where
    <ea> is one of the addressing modes listed below

Operation:

    <ea> --> PC

Description:

    Execution resumes at <ea>.

    If jmp follows a rorg directive, a jump to memory abso-
lute is converted to a branch.

Example:

```
            jmp here
            jmp r(0:0)
here:       jmp (1:150)@
```

Addressing Modes:

    <ea>: m,r,mi,pcr

Format:

| 0250 | | P | { | H8A2 | ... | H85A4 | } | operands |

Syntax:

    bra <ev>

    where:
    <ev> is one of the addressing modes listed below

Operation:

    PC + <ev> --> PC

Description:

    Execution resumes at the sum of the program counter and the
effective value.

Example:

                    bra 100

Addressing Modes:

    <ev>: a,r

Format:

    |0250| |P| |H8A5| ... |H8A6| } |operands|

Syntax:

      if R <rop> <ev>,M
      if <bop> <ea>,M

      where:
      <rop> is a relational operator
      <bop> is a test operator ·
      <ea> and <ev> are one of the addressing modes listed below

Operation:

      if R <rop> <ev> then
            M --> PC

      if <bop> <ea> then
            M --> PC

Description:

      If the comparison is true, execution resumes at M; other-
wise,with the next instruction.

Example:

```
              move {int,10},r(0:0)
    loop:     if   r(0:0) < {int,1},done
              sub  {int,1},r(0:0)
              jmp  loop
    done:     if   int data,loop

    data      ds   1
```

Addressing Modes:

      R: r

      <ev>: r,i

      <ea>: r,m

      M: m,pcr

Format:

      | 0250 | | P |

      { | 58A7 | , | 58A8 | , | 58AB | , | 58AC | , | 48AF | , | 48B0 | , | 48B3 | , | 48B4 | }

      | operands |

Syntax:

```
    if R <rop> <ev>,Mx,My
    if <bop> <ea>,Mx,My
```

    where:
    <rop> is a relational operator
    <bop> is a test operator
    <ea> and <ev> are one of the addressing modes listed below

Operation:

```
    if R <rop> <ev> then
            Mx --> PC

    else

            My --> PC

    if <bop> <ea> then
            Mx --> PC

else

            My --> PC
```

Description:

    If the comparison is true, execution resumes at Mx;
otherwise, at My.

Example:

```
            if    r(0:0) > r(0:1),case1,case2
    stuff:  move  r(0:0),data
    case1:  jsr   first,s(0)
            if    int r(0:0),case1
            stop
    case2:  jsr   second,s(0)
            stop
```

Addressing Modes:

    R: r

    <ev>: r,i

    <ea>: r,m

    Mx: m,pcr

    My: m,pcr

347

Format:

| 0250 | | P |

{ | 68A9 | , | 68AA | , | 68AD | , | 68AE | , | 58B1 | , | 58B2 | , | 58B5 | , | 58B6 | }

| operands |

Syntax:

    jsr <ea>,S

    where:
    <ea> is one of the addressing modes listed below

Operation:

    PC --> S
    <ea> --> PC

Description:

    The program counter is pushed onto stack S, and execu-
tion resumes at <ea>.

    Following a rorg directive, memory absolute is converted
automatically to program counter relative.

Example:

                jsr   incr,s(0)

Addressing Modes:

    <ea>: m,mi,r,pcr,S: s

Format:

    | 0250 | | P | { | H8B7 | ... | H8B9 | } | operands |

Syntax:

    bsr <ev>,S

    where:
    <ev> is one of the addressing modes listed below

Operation:

    PC --> S
    PC + <ev> --> PC

Description:

    The program counter is pushed onto stack S, and execu-
tion resumes at the sum of the program counter and <ev>.

Example:

                    bsr   r(1:0),s(0)

Addressing Modes:

    <ev>: r,a S: s

Format:

    |0250| |P| { |38BA| , |38BB| } |operands|

Syntax:

    rts S

Operation:

    S --> PC

Description:

    Execution resumes at the address popped from stack S.

Example:

    incre: add   {int,1},r(0:0)
                    rts   s(0)

Addressing Modes:

    S: s

Format:

    | 0250 | | P | | 28BC | | operand |

Syntax:

    open S

Operation:

    S -->

Description:

    To open a file, four file parameters must be pushed on
the stack, in proper order, before the open instruction is
invoked. These attributes are: a string atom for the
filename, a file descriptor atom, an integer atom for the
access mode, and an integer atom for the data type (raw or
AM typed values). The open instruction pops these parameters
off the stack and opens the file. All future file operations
are referenced by the file descriptor.

Example:

    datafile   equ {file,3}
                    push {string,"filename"},s(0)
                    push {datafile},s(0)
                    push {int,0},s(0)
                    push {int,0},s(0)
                    open s(0)

Addressing Modes:

    S: s

Format:

    |0250| |P| |28C0| |operand|

352

Syntax:

    close S

Operation:

    S -->

Description:

    The file descriptor atom must first be pushed on the stack.
The close instruction pops the stack and closes the file.

Example:

    datafile   equ   {file,3}
                    push   {datafile},s(0)
                    close s(0)

Addressing Modes:

    S: s

Format:

    |0250| |P| |28C1| |operand|

                              353

Syntax:

    read S

Operation:

    S -->

Description:

    The file descriptor atom must first be pushed on the stack.
The memory address atom for the destination buffer cell is
pushed next. The read instruction pops these parameters off
the stack and puts the next file cell in the destination
buffer.

Example:

```
datafile        equ    {file,3}
                push   {datafile},s(0)
                push   {addr,data},s(0)
                read   s(0)
data            ds     100
```

Addressing Modes:

    S: s

Format:

    |0250| |P| |28C2| |operand|

Syntax:

    write S

Operation:

    S -->

Description:

    The file descriptor atom must first be pushed on the stack.
The memory address atom for the source buffer cell is pushed
next. The write instruction pops these parameters off the
stack and puts the contents of the source buffer cell into
the next file cell.

Example:

```
datafile      equ    {file,3}
              push   {datafile},s(0)
              push   {addr,data},s(0)
              write  s(0)
data          dc     {string,"hello world"}
```

Addressing Modes:

    S: s

Format:

    | 0250 | | P | | 28C3 | | operand |

Syntax:

    write<ea>,Q

    where:
    <ea> is one of the addressing modes listed below

Operation:

    Source --> Q

Description:

    The source value is written onto queue Q. The programmer
has no access to the queue pointer.

Example:

    write {nat.17},q(0)
    write r(0:10), q(1)

Addressing Modes:

    <ea> : m,r,i,q

    Q: q

Format:

    |0250| |P| { |H890| ... |H897| } |operands|

Syntax:

    read Q,<ea>

    where
    <ea> is one of the addressing modes listed below

Operation:

    Q --> destination

Description:

    The source value is read from the queue Q and stored at
<ea>. The programmer has no access to the queue pointer.
It is an error to attempt to read a value from an empty queue.

Example:

```
              read  q(0),r(0:1)
              read  q(0),data
data:         dsl
```

Addressing Modes:

    Q: q

    <ea> : m,r

Format:

    $\boxed{0250}$ $\boxed{P}$ { $\boxed{H899}$ ... $\boxed{H89f}$ } $\boxed{\text{operands}}$

357

Syntax:

    delete Q

Operation:

    Q -->

Description:

    The front value of queue Q is removed. It is an error
to attempt to remove the front value of an empty queue.

Example:

                delete q(0)

Addressing Modes:

    Q: q

Format:

    | 0250 | | P | | 2898 | | operands |

Syntax:

    open D

Operation:

    D -->

Description:

    A database identifier is required to open the databse.
All future operations are referenced by this identifier.

Example:

                    open {database,databaseid}

Addressing Modes:

    D: i

Format:

    |0250| |P| |28C4| |operand|

CLOSE   Close the Database   CLOSE

Syntax:

    close D

Operation:

    D -->

Description:

    The database identifier is required to close the database.

Example:

                         close{database,databaseid}

Addressing Modes:

    D: i

Format:

    | 0250 | | P | | 28C5 | | operand |
